It is suggested by the committee that members of the American Anthropological Association having occasion to describe clay vessels may classify them: first, as to material, as consisting of clay, sand, shell and their combinations, and as possessing certain general ground-color; second, as to manufacture, as sun-dried or fired, as coiled or modeled—with the variations and steps of each process; third, as to form; fourth, as to decoration, as plain, stamped, incised or painted. With regard to form the committee begs to offer the following definitions and suggestions in classifications.

In all cases measurements are considered as referring to an upward direction.

A simple vessel must consist of a body and may have a rim, neck, foot, handle or any combination.

(1) Body: A formation capable of holding within itself a liquid or a solid substance.

(2) Rim: (A) A part of the vessel forming the termination of the body. (B) A part of the vessel recognizable by a change in the thickness of the material in the terminal sections.

(3) Neck: A part of the vessel recognizable by a more or less sudden decrease in the rate of increase or decrease of the diameter.

(4) Foot: An attachment to the vessel which serves as the support to the body when upright.

(5) Handle: A part of the vessel consisting of some outside attachment, not serving as support.

Body.—It is suggested that in comparing the forms or cross-sections of vessels particular attention be paid to the proportion of the diameter to the height, to the rate of change of this proportion, to the place of change of direction in this proportion and to refer to the following definitions of the two dimensions:

Height: The distance from the base to a horizontal plane passing through the most distant part of the rim.

Diameter: The distance from any one point on the sides to any opposite point on the sides measured on a plane at right angles to the height.

Base: The point of contact or a plane of contact of the body with a horizontal surface.

Types: Body.—These are so various, depending on relative height and diameter of the cross-section, that an analysis is too cumbersome to be of service to general reference.

Neck.

1. Expanding.
2. Cylindrical.
3. Contracting.
4. Combinations.

Lip.—A part of the neck or body recognizable by a suddenly increasing diameter of neck or body, that continues increasing to the rim.

Foot.—1. Continuous.

- (A) Expanding.
- (B) Cylindrical.
- (C) Contracting.
- (D) Combinations.

Feet.—2. Not continuous.

Differentiated by

- (A) Number.
- (B) Angle with the horizontal.
 - (a) Expanding upward.
 - (b) Perpendicular.
 - (c) Contracting upward.

Handles.—Types.

Differentiated by

1. Number.
2. Position on the vessel.
 - (A) Body.
 - (B) Neck.
 - (C) Foot.
 - (D) Combinations.
3. Form.
 - (A) Continuous with body or neck.
 - (B) Not continuous with body or neck.
 - (a) With constant direction.
 - (b) With varying direction.
 - (c) With reentry upon vessel.
 - (A') Round.
 - (B') Flat.
 - (C') Coiled.

ARTICLES IN STONE

Chipped Stone

I. Knives and projectile points.

Larger = 5 cm. (2 inches) or more in length.

Smaller = less than 5 cm. (2 inches) in length.

Types.

1. Without stem.
 - (A) Without secondary chipping (=flakes).
 - (B) With secondary chipping.
 - (a) Pointed.
 - (a') At one end.
 - Base concave.
 - Base straight.
 - Base convex.
 - Sides convex.
 - One side convex.
 - One side straight.

(b') At both ends.

(b) Ends convex.

(c) More or less circular.

2. With stem.

(A) Stem expanding from base—with or without barbing.

(a) Base concave.

(b) Base straight.

(c) Base convex.

(B) Stem with sides parallel—with or without barbing.

(a) Base concave.

(b) Base straight.

(c) Base convex.

(C) Stem contracting from base—with or without barbing.

(a) Base concave.

(b) Base straight.

(c) Base convex.

Note 1. The proportion of the length of the base to its breadth should be observed.

Note 2. The notches in barbed specimens may be vertical, horizontal or with varying diameter.

Note 3. The angles formed by the faces (i. e., "bevel") should be observed.

II. Scrapers.

Types.

1. With one or more scraping edges.
2. Without or with notch (including circular).

III. Perforators.

Types.

Differentiated by

1. Cross-section.
 - (A) Round.
 - (B) Quadrangular or irregular.
2. Stem.
 - (A) Without stem.
 - (B) With stem.
 - (a) Stem expanding gradually.
 - (b) Stem expanding suddenly.

IV. Hammerstones.

Types.

1. Spheroidal.
2. Discoidal.
 - (A) "Pitted."
 - (B) Not "pitted."
3. Elongated.
 - (A) Grooved.
 - (B) Not grooved.

Note 1. Practical or ornamental serration may be applied to many forms.

Note 2. Combinations of the types may appear in one specimen and any type may be infinitely varied by individual caprice.

Ground Stone

I. Geometrical forms.

(i. e., flat "spuds," "gorgets" and pendants).

(a) Spade-shaped.

(b) Ovate.

(c) Sides concave (not common).

(d) Sides straight.

(e) Sides convex.

(f) Leaf-shaped.

(g) Spear-shaped.

(h) Rectangular.

(i) Sides concave.

(j) Sides straight.

(k) Sides convex.

(l) Shield-shaped.

(m) Pendants.

(a) Celt-shaped.

(b) Rectangular.

(c) Oval or circular.

Resemblances to known forms.

(A) Animal-shaped stones.

(B) Boat-shaped stones.

(C) Bar-shaped stones.

(a) Longer, resembling true "bars."

(b) Shorter, "ridged" or "expanded gorgets."

(D) Spool-shaped stones.

(E) Pick-shaped stones.

(F) Plummets-shaped stones.

(G) Geometrical forms.

(a) Spheres.

(b) Hemispheres.

(c) Crescents.

(d) Cones.

3. Perforated stones with wings.

(A) Wings with constant rate of change of width.

(a) Wings expanding from perforation.

(b) Wings with sides parallel.

(c) Wings contracting from perforation.

(B) Wings with varying rate of change of width.

II. Tubes and tube-shaped stones.

III. Beads.

IV. Pitted stones other than hammer-stones.

The committee finally takes pleasure in thanking the following members for assistance rendered:

Professor N. H. Winchell, University of Minnesota, Minneapolis; Professor Henry Montgomery, University of Toronto, Toronto; Professor Wm. N. Bates, University of Pennsylvania, Philadel-

phia; Dr. H. Kinner, St. Louis, Mo.; Dr. George Grant MacCurdy, Yale University, New Haven; Mr. W. Raymond Harrington, New York; Mrs. Zelia Nuttall, Coyoacan, D. F., Mexico; Mr. C. C. Willoughby, Harvard University, Cambridge; Dr. Walter Hough, National Museum, Washington; Dr. Nicholas León, Mexico; Mr. F. S. Dellenbaugh, New York; Professor F. W. Putnam, Harvard University, Cambridge; Dr. John M. Wulfin, St. Louis; Mr. H. I. Smith, American Museum of Natural History, New York; Rev. J. D. Marmor, New York; Mr. Christopher Wren, Plymouth, Pa.; Dr. A. W. Butler, Indianapolis; Dr. H. W. Shimer, Boston; Professor W. H. Holmes, Washington; Mr. Richard Herrmann, Dubuque, Iowa; Dr. H. F. ten Kate, Tokio; Dr. J. B. Ambrosetti, Buenos Aires.

The committee was continued and asked to collate the terminology already in use.

The report of the Committee on Concordance of American Mythologies was accepted as read by Professor Boas, chairman, and the committee was continued.

Mr. F. W. Hodge's report as chairman of the Committee on Linguistic Families North of Mexico was accepted and the committee continued. In this connection it was moved and carried that whenever an author uses a term not acceptable to the committee the editor be instructed to add in parenthesis the term approved by the committee. Mr. Hodge also reported for the Committee on Book Reviews, of which he is chairman. The report was accepted and the committee discharged at their own request and with a vote of thanks for their labors on the part of the association.

Dr. George A. Dorsey, recently returned from a year's stay in the far east, gave an interesting account of his journey through New Guinea. The Papuans of New Guinea are very different physically from the natives of New Britain. The various forms of head-dress were described; also the splendid character of the pile dwellings that are such a striking feature of the coast region. Mention was made of the wooden drums five to fifteen feet in length, great adzes of stone and shell, wooden bowls carved to represent animals, the canoes, etc. All are expert canoe men. The usual form is the outrigger carrying sails and often of great size.

The Big River (Kaiserin Augusta) was ascended for a distance of 110 miles, where it was still as large as and deeper than the Mississippi at St. Louis. The country is flat and covered by extensive forests. Twenty villages (sago gatherers)

were passed. The sago palm is cut down near the ground and the top lopped off; the trunk is split and the mass of sago broken up by means of a cylindrical stone set as an adz. The houses differ from those along the coast. They are built on piles, to be sure; instead of being squarish, they are long, narrow and absolutely open at each end. This is to provide ventilation, as the natives sleep in long mosquito-proof, tightly woven rattan bags. There is usually an altar with human images. Human skulls (of relatives) are placed on the floor in front of these altars. The canoes are carved at one end to represent the alligator.

"Geological Facts bearing on the Place of the Origin of the Human Race" was the title of a paper by Professor George Frederik Wright. It is becoming more and more clear that the glacial period was ushered in by a general land elevation over all the northern hemisphere (if not the whole world). All the high mountains of the world bear Tertiary strata at elevations of several thousand feet. The effect of such elevation would be to enlarge the continental area around all their borders and form land connection between north-western America and northeastern Asia and possibly between Greenland and northern Europe. It would also connect North America with South America through the West Indies, and Europe with Africa across the Straits of Gibraltar and the shallow belt extending south from Sicily. That there was such a land connection appears from the fact that at the close of the Tertiary period, as the glacial epoch was approaching, there was a remarkable intermingling of the fauna of these connected regions. The elephant and rhinoceros came over from Africa and wandered as far north as Yorkshire, England. The megalonyx and some other South American species wandered into North America as far as Ohio, while the mammoth spread from central Asia across Siberia to northwestern America and wandered to the Atlantic coast and borders of Mexico.

Cumulative evidence seems to point to central Asia as the center from which man was dispersed in company with the mammoth over the entire northern hemisphere. Central Asia seems to have been the earliest center of civilization. Here in the ancient valley of the Oxus, according to Pompeii, there are ruins of cities which reach back to 8000 B.C., and here, beyond reasonable doubt, the Aryan family of languages had its origin.

A study of the physical changes which passed over this region contemporaneously with those in northern America and Europe during the glacial period and the now undoubted connection of man

with the glacial period, render very plausible the hypothesis that the changes connected with that period were a contributory cause of the dispersion of mankind from this Asiatic center. Recent investigations show that, during the glacial period, central Asia offered a specially favorable area for the development of man together with both the vegetable and animal species upon which he is dependent for means of sustenance. The whole region is dependent upon irrigation, which is secured by the flow of water which comes down from the melting ice and snow on the lofty mountain heights. At the present time this irrigated belt is a very large one, but during the glacial period when the ice came several thousand feet lower down on the mountains (but never to the plains), the irrigated areas were immensely larger, furnishing sustenance for an indefinitely larger population. But at this time all northern Europe and northern America were enveloped in glacial ice. But as the glacial period declined the supply of water from the mountains of central Asia diminished and the oases contracted so as greatly to curtail the field of human occupation. Contemporaneously with this curtailment in central Asia the fertile plains of Europe and North America were opened to occupation by the melting of the ice, so that streams of emigration entered both Europe and North America from this common center. In America the Aryan-speaking races are just entering upon this glacial inheritance. It certainly means a great deal in the settlement of the question of the origin of the human race that we have so many classes of facts pointing to this conclusion or at least coinciding with this theory.

Professor Wright also presented for inspection three implements recently found, supposed to be of glacial age. The first was one already described by Miss Luella A. Owen in the sixth volume of "Records of the Past." The evidence is perfectly satisfactory that it was found in undisturbed loess at St. Joseph, Mo., thirty feet or more below the surface. The second was found in the bottom of a pit where the loess was being excavated two or three miles above St. Joseph, and in all probability came from the loess. Both these implements are of paleolithic type and the patina upon them and the oxidation of the surface indicate great age. The third implement, which is of a familiar paleolithic type, was found in a gravel pit excavated in a "kame terrace" on the border of the River Styx in Wadsworth, Madina County, Ohio. But it was found on the floor of the pit so that the evidence is not definite

as to its position in the undisturbed gravel, but everything about it is consistent with its glacial age and it is different in almost every respect from the great number of implements found on the surface in that locality. Its character is confirmed by the fact that in a farmer's collection near by another implement almost precisely like it was found and reported to have been from this same gravel deposit a short distance away.

"Characteristic Traits of the Yana Language of California." The Yana language of northern California represents a distinct linguistic stock and was spoken in three dialects (north, central and south), of which one (south) is now extinct. Phonetically it is characterized by the presence of intermediate, aspirated surd and "fortis" stops, by a weakly trilled r, by voiceless l, m, n and r, and by doubled (long) l, m and n. Phonetic processes of morphological significance are vocalic changes in the verb stem in the formation, e. g., of causatives and passives, and the change of l to n in nouns to form the diminutive.

There are two main forms of speech in Yana, one used by men speaking to men, the other in all other cases; the second form is differentiated from the first partly by phonetic, partly by formal modifications. Morphologically Yana is characterized by having practically only two parts of speech—noun and verb (adjectives, numerals, interrogative pronouns and adverbs, and conjunctive elements are all morphologically verbs). The pronominal elements (possessive and subject) are, in the main, identical in both noun and verb, a grammatical differentiation of these parts of speech being brought about largely by syntactic means. The structure of the verb is rather complicated. Besides pronominal suffixes and tense and mode suffixes, all of which are more strictly formal in character, we have stems of first position, which may, in many cases, be directly employed with the requisite formal suffixes, stems of second or other position, which can not be used without a preceding stem of first position, and an immense number of derivational suffixes (local, temporal, relational, quasi-modal, etc.). The total number of non-formal elements that follow stems of first position is easily over three hundred. Prefixes do not occur in Yana.

Mrs. Zelia Nuttall spoke of "A Curious Survival in Mexico of the Use of *Murex purpurea* for Dyeing Purposes," producing by way of demonstration two woven fabrics colored purple. The industry is known to exist in Nicoya, Costa Rica. Hartman found it also on the Peninsula of Guanaacosta (Costa Rica).

Drs. Charles Peabody and George Grant MacCurdy made a "Presentation of Eoliths from Boncelles," near Liège, Belgium, they having visited that station together last summer. Boncelles lies in the Ardennes at a height of 265 meters above the sea. Here M. de Munck discovered eoliths in a flinty layer surmounted by a thick deposit of upper Oligocene sands. The age of the latter is determined by numerous fossil shells, including *Cytherea beyrichi*, *Peotunculus obovatus* and *Cardium*. According to Rutot the deposit in which the eoliths occur is of middle Oligocene age. The Boncelles eoliths are therefore older than those of Cantal.

Another paper dealing with European archeology, "Some Recent Paleolithic Discoveries," was presented by Dr. George Grant MacCurdy. This paper appeared in the October-December issue of the *American Anthropologist*.

The papers by Dr. C. Hart Merriam: "Mythology of the Mewan Tribes," "Additional Notes on the Yumme or Mourning Ceremony," "The Creation Myth of the Pa-we-nan" and "Battle of the First People with Dakko, the Sun God—a Hamfo Myth," will appear in the *Journal of American Folk-Lore*.

Mr. Stansbury Hagar discussed "Izamal and its Celestial Plan." At Izamal in the north-central part of Yucatan are found a group of ruins which mark the site of an ancient theogonic center of the Mayas. Landa, writing in the latter half of the sixteenth century, gives the earliest reference to them. He mentions eleven or twelve edifices and describes one. Lizana, writing sixty years later, found only five edifices, but he gives us a detailed description of their comparative location and of the traditions associated with them which reveals the basic plan of Izamal. This plan is confirmed by details supplied by the modern travelers, Stephens, Norman, Charnay, Le Plongeon and Holmes.

Lizana says that the buildings were temples; they stood upon the summit of pyramidal mounds typical of Mexico and Central America, as well as Yucatan. Towards the north was the highest temple, called Kinich Kakmo, Sun-Eye and Ara or Parrot of Fire, because the sun was supposed to descend upon it at noon and to consume the offerings upon its altar, as the fiery plumed ara descends from the sky. These symbols were associated with the time of the June solstice.

The Mayan ritual refers to the descent of an "angel" upon the altar at this time and to the new fire festival. A similar Mexican tradition mentions the descent of a bird in a luminous

constellation. The symbolism therefore seems to refer to the annual descent of the sun from the sign Cancer, the northernmost point in the solar journey, at the solstitial noon of the year.

Towards the west was the mound and temple dedicated to Itzamna as lord of the dead. It contained the image of a hand, because on this spot Itzamna healed those who were ill and restored the dead to life by laying his hand upon them, whence it bore the name Cab-ul the Working Hand. In this aspect Itzamna may be identified with the death god A of the codices who rules the Mayan uinal Xul or End in October-November and represents Scorpio, the death sign.

Towards the southwest was the temple of Hun-pictok, the Warrior, or the Commander of Eight Thousand Lances. This was an arsenal and the headquarters of the army. Beside one of the two colossal heads upon the facade of this pyramid may still be seen the double spiral xonescuilli symbol which connoted the sign and constellation Sagittarius for the Mexicans. It also referred to the gods of war, and to Orion the Warrior, who represented Sagittarius as a catasterism.

At the south stood the temple of Itzamna in the aspect of the Cosmic Spirit, represented in the codices by the god D and the sign Capricornus.

Finally Lizana describes the temple called Papp Hol Chac, House of Heads and Lightnings. He does not locate it, but Charnay writes of it as facing the Kinich Kakmo pyramid from the south. In it dwelt the priests who administered justice and foretold the future. Apparently the reference is to the tlantouani or diviner of the Mexicans, Maya chilan, who imparts the wisdom supposed to be obtained from the spirits of the dead, and who is associated with the constellation Teoyacatlatohua, our Libra-Scorpio. In this instance the former sign seems to be represented. Lizana also mentioned four roads which extended from Izamal towards the cardinal points.

Each of the five edifices described by Lizana was associated with a zodiacal sign. Their relative positions correspond correctly to those of the signs they represent. The original plan of Izamal consisted of twelve temples each representing a zodiacal sign in its proper relative position in the zodiacal circle. These structures were grouped around an undefined central space from which the four roads divided the country into four provinces corresponding to the celestial and cosmical quartering of the solar path by the solstices and equinoxes. The basis of this plan was therefore the imitation upon earth of the supposed celestial plan. It is identical with the plan of Cuzco, the

Inca capital,² a plan most appropriate to a sacred city of priests who watched the stars. The zodiacal symbols repeat throughout those of Peru, indicating intercommunication, direct or indirect, between the Mayas and the Peruvians at some time.

In "Social Institutions of the Tinguayan Igorotes," Mr. Daniel Folkner gave some of the results of his work for the Ethnological Survey of the Philippine Islands while Lieutenant Governor of Bontoc.

The following papers were read by title:

Measurements of Mixed and Full-Blooded Dakota Children: Dr. CLARK WISSLER.

Height in the American Indians: Dr. ALDO HEDLIČKA.

Memorial Address for Otis T. Mason: Dr. WALTER HOUGH.

Archeological Explorations in Manitoba: Professor HENRY MONTGOMERY.

Some Inventions of the Ancient Hawaiians: Mr. WILLIAM A. BRYAN.

Committee Report on the Preservation of American Antiquities: Dr. E. L. HEWETT (Secretary).

Ballads and Songs of Western North Carolina: Miss LOUISE RAND BASCOM.

Folk-Lore from the Southern States: Dr. JOHN P. CROSS.

Folk-Music in America: Mr. PHILLIPS BARRY.

Notes on the Northern Wintun Indians: Mr. F. B. WASHINGTON.

Traditions of the Coos Indians of Oregon: Mr. LEO FORCHRENEBERG.

Observations on Esoteric Narratives on the Sources of Myths: Dr. CLARK WISSLER.

Sketch of the Yuchi Language: Dr. FRANK E. SPECK.

Songs of the Western Cowboys: Mr. GEORGE WHEEL.

The Importance of Recording Negro-Lore, Dialects and Melodies: Miss MARY W. F. SPEERS.

GEORGE GRANT MACCUBERT,
Secretary

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE SECTION K—PHYSIOLOGY AND EXPERI- MENTAL MEDICINE

SUMMARY OF THE PROCEEDINGS

THERE were two meetings of the section in the auditorium of the physiological building at the Johns Hopkins Medical School during convocation week, as follows:

² See author's paper on "Cuzco, the Celestial City," in *Proceedings of the International Congress of Americanists*, New York, 1902.

First Session.—Tuesday afternoon, December 29, 1908. Presiding officer: Vice-president William H. Howell. The program consisted of: (1) an address by the retiring vice-president, Ludvig Hektoen, on Opsonins and other Antibodies,¹ and (2) a symposium on The Regulation of Physical Instruction in Schools and Colleges from the Standpoint of Hygiene.

Second Session.—Wednesday afternoon, December 30, 1908. Presiding officer: Vice-president William H. Howell. Joint session with the American Physiological Society, the Society of American Bacteriologists and the American Society of Biological Chemists. This session was devoted to three general papers (see scientific proceedings below).

EXECUTIVE PROCEEDINGS

The following officers were elected for the ensuing term:

Vice-president of the Association and Chairman of the Section—Charles Sedgwick Minot.

Secretary—George T. Kemp.

Sectional Committee—William H. Howell, vice-president, 1908-9; Charles Sedgwick Minot, vice-president, 1909-10; George T. Kemp, secretary, 1909-13; Frederick G. Novy (one year), Graham Lusk (two years), Jacques Loeb (three years), E. P. Lyon (four years), William J. Gies, secretary 1904-9 (five years).

Member of the Council—W. G. MacCallum.

Member of the General Committee—William W. Ford.

SCIENTIFIC PROCEEDINGS

I. FIRST SESSION.—(1) Vice-presidential address and (2) symposium on college athletics.

Program

Address by the retiring chairman, Dr. Ludvig Hektoen, professor (and head of the department) of pathology and bacteriology, University of Chicago. Subject: Opsonins and other Antibodies.²

Symposium—Subject: "The Regulation of Physical Instruction in Schools and Colleges from the Standpoint of Hygiene."

Introductory remarks by the chairman, Dr. William H. Howell, professor of physiology, and dean, Johns Hopkins Medical School.

The Regulation of Physical Instruction in Schools and Colleges from the Standpoint of

Hygiene: Dr. R. Tait McKenzie, professor of physical education, University of Pennsylvania.

On the Physiological Effects of Moderate Muscular Activity and of Strain: Dr. Theodore Hough, professor of physiology, University of Virginia.

Physical Exercise from the Standpoint of Physiology: Dr. Frederic S. Lee, professor of physiology, Columbia University.

Departmental Organization for the Regulation of Physical Instruction in Schools and Colleges from the Standpoint of Hygiene: Dr. Thomas A. Storey, associate professor and director of physical instruction, College of the City of New York.

General discussion.

II. SECOND SESSION.—General papers in joint session with the American Physiological Society, the Society of American Bacteriologists and the American Society of Biological Chemists.

Program

Anaphylaxis: Dr. M. J. Rosenau, director of the hygienic laboratory, Public Health and Marine Hospital Service, U. S. A., Washington.

The Physiological Significance of Creatin and Creatinin: Dr. Lafayette B. Mendel, professor of physiological chemistry, Sheffield Scientific School, Yale University.

The Venous Pulse: Dr. Albion W. Hewlett, professor of the theory and practise of medicine and clinical medicine, University of Michigan.

General discussion.

PAPERS AND ABSTRACTS (I. AND II.)

I. Papers comprising the symposium on The Regulation of Physical Instruction in Schools and Colleges from the Standpoint of Hygiene. By Drs. Mackenzie, Hough, Lee and Storey. (To be published in SCIENCE, March 26 and April 2.

II. Papers comprising the program of the joint session with the bacteriologists, biochemists and physiologists. By Drs. Rosenau, Mendel and Hewlett.

Anaphylaxis: M. J. ROSENAU. (Will be published in the *Archives of Internal Medicine*.)

The Physiological Significance of Creatin and Creatinin: LAFAYETTE B. MENDEL. (Will be published in SCIENCE.)

The Venous Pulse: ALBION WALTER HEWLETT.

The typical venous pulse consists of three main waves which have been designated the *a*, *c* and *v* waves, respectively. A comparison of the jugular pulse with that of the carotid artery shows that the *c* wave occurs almost simultaneously with the carotid pulse. The *a* wave precedes the *c* wave

¹ See SCIENCE, Vol. XXIX., p. 241, 1909.

² See SCIENCE, Vol. XXIX., p. 241, 1909.

by an interval of about 0.18 second. It is caused by the contraction of the auricle. In some tracings the *a* wave is very prominent, greatly overshadowing the succeeding *c* wave. This was noted particularly in patients with more or less decompensation, though it is not pathognomonic of such conditions.

The *c* wave occurs almost simultaneously with the carotid pulse and in some instances it is caused by a transmitted arterial pulsation. The earlier writers, especially Francois Franck, Fredericq and Gerhardt regarded the *c* wave as a true venous wave, but Mackenzie and Wenckebach believe that it is always a carotid pulse. Recent investigations, however, tend to show the correctness of the earlier views; for, (1) the *c* wave can often be recognized by inspection as being present in the veins themselves, (2) it often precedes the carotid pulse by about 0.02 second, (3) it has a different form, (4) it can occasionally be demonstrated on liver tracings, and (5) in pathologic venous tracings, especially from cases of auricular paralysis, the *c* wave on the jugular differs in size from the radial pulse, often being largest when the radial is smallest. In most tracings, therefore, the *c* wave is of venous origin; when of arterial origin, this is generally indicated by its form.

The venous *c* wave is probably to be referred back to the momentary increase in intra-auricular pressure which occurs at the onset of ventricular systole. This wave of increased pressure appears somewhat later in the neck on account of the slow transmission of venous waves.

The negative wave following the *a* wave is undoubtedly due to auricular diastole. That following the *c* wave may also be explained in part by auricular diastole; but it is evident (1) from heart block tracings and (2) from tracings of auricular paralysis from man and from animals that ventricular systole alone is capable of causing a negative wave in the venous pulse just after the *c* wave. This is caused by the descent of the ventricular base during systole, which opens up the auricle on its attachments to the great veins.

Tracings from a patient with palpitation showed a very marked *c* wave and a very marked depression immediately following. As other venous waves were merely indicated on the tracing, it seems probable that the earlier movements of the ventricle during systole were executed with unusual speed.

The *v* wave appears in the neck just after the time of the dicrotic notch on the arterial pulse.

Owing, however, to the slow transmission of venous waves the *v* wave begins in the heart at a somewhat earlier period, probably in late systole, and it is terminated there by the opening of the tricuspid valves. It is probably due partly to the replacement of the base of the ventricle toward the auricle at the onset of diastole. It is also due in part to the accumulation of blood in the auricle during the closing of the tricuspid valves. The *v* wave is accentuated in conditions of auricular stasis especially in tricuspid insufficiency and auricular paralysis.

The negative wave following the *c* wave is due to the opening of the tricuspid valves and the consequent flow of blood toward the ventricle. It is especially pronounced in conditions of auricular stasis. In slowly acting hearts this negative wave is often followed by a shoulder on the venous tracing which seems to be due to a recoil from the rapid filling of the ventricle.

WILLIAM J. GIES,
Secretary

SOCIETIES AND ACADEMIES

THE WASHINGTON ACADEMY OF SCIENCES

DR. ALFRED G. MAYER, of the Carnegie Institution of Washington, delivered an address before the Washington Academy of Sciences Tuesday evening, February 23, on "The Tortugas Marine Laboratory, its Scope and Aims." Dr. Mayer kindly furnished the following abstract of his address:

"The lecturer called attention to the fact that this laboratory is the only permanent marine station within the American tropics, and that the generous support accorded to it by the Carnegie Institution of Washington had enabled it to develop into the best equipped marine laboratory in the tropical world.

"The seven Tortugas Islands are out in the Gulf of Mexico, seventy miles west of Key West, and consist of coarse wave-washed and wind-blown fragments of marine shells, which afford no soil suitable for the growth of mangroves; and thus the laboratory is unique in being the only place on the seaboard of Florida which is free from endemic mosquitoes in summer.

"Along the mainland coast of southern Florida the winds cause the waters over the coral flats to be churned into a silky mass of suspended silt, which is fatal to pelagic life, but at Tortugas, owing to the great area of deep ocean water in their neighborhood and the small size of the coral

plateau around them, this is not the case. The islands lie on the leeward side of the Gulf Stream, and the rich pelagic life of the great tropical current is constantly drifted upon their shores.

"Expeditions have for generations brought tons of preserved specimens of tropical forms home to our museums and colleges, where they have been studied and named, but as yet we know sadly little of the living animals of the tropics, their habits, development and physiology. The laboratory, therefore, aims chiefly to encourage research in these new fields, and to this end many of our leading investigators and most promising young workers in research have been invited to pursue their studies at Tortugas.

"The laboratory is now entering upon its fifth year. Two volumes of its researches have been published by the Carnegie Institution, and ten other papers have been published in various scientific journals, and the amount of research work now in press greatly exceeds that yet published.

"The lecturer then reviewed some of the more generally interesting, although not necessarily the most important, researches, as follows: The late Professor William K. Brooks, of Johns Hopkins University, carried out interesting studies of the pelagic *Solfa* of the Tortugas, his papers being excellently illustrated by the drawings made by Mr. Carl Kellner. Brooks and McGlove find that the lung of the prosobranchiate gastropod *Ampullaria* is developed out of a thickening, or ridge, of the epithelium of the mantle, and arises simultaneously with the gill and osphradium, all three being homologous organs. There is probably no phylogenetic relationship between the lung of *Ampullaria* and that of the pulmonates. *Ampullaria* is a large brown snail which lives in the fresh water of the Everglades, and lays eggs in pearl-like clusters on the stems of grasses above the water-line.

"Mr. Frank M. Chapman, of the American Museum of Natural History, describes the nesting habits of the booby (*Sula leucogastra*) and of the frigate bird (*Fregata aquila*) upon the isolated rocky island of Cay Verde in the Bahamas. Permission to study these birds was generously granted by his excellency, Sir William Grey-Wilson, in his official capacity as governor-in-council of the Bahamas. Specimens for a 'group' of the frigate birds were collected and these are now beautifully displayed in the American Museum in New York. Mr. Chapman found the nesting season of both boobies and frigate birds to be at its height early in April, the birds having

apparently come to the island to nest in February. He found that the boobies always lay two eggs, but rear only one young bird.

"Professor Edwin G. Conklin, of Princeton University, studied the structure of the egg of the 'thimble jellyfish,' *Lirergus mercurius*, which appears in vast breeding swarms upon the surface in the spring at Tortugas, and the Bahamas. He discovered that these medusæ always spin in an anti-clockwise direction as they progress through the water if viewed from the oral pole. The eggs consist of three easily distinguished substances. A peripheral layer of clear protoplasm which becomes the peripheral layer of the embryo and gives rise to the cilia, an intermediate layer of closely crowded yolk spherules which constitute the principal parts of all of the cells of the gastrula and blastula, and an inner mass of dissolved yolk which is poured into the cleavage-cavity and probably serves as a source of nourishment.

"Dr. R. P. Cowles, of Johns Hopkins, made an elaborate study of the habits of the 'ghost crab,' *Ocypoda arenaria*, and finds that it probably can not distinguish color as such but detects simply a difference between light and shadow. It can form simple associations and displays memory. It has apparently no sense of hearing, but its otocysts are organs of equilibration. It changes color under the influence of light and temperature, but this change does not occur if the crab's eyes be blackened.

"Dr. H. E. Jordan, of the University of Virginia, carried out a very elaborate series of studies upon the histological structure of the eggs of echinoderms and of the walking-stick-insect, *Aplopus*. The germinal spot in echinoderm eggs appears to be in part at least a storehouse of material which is to contribute in the formation of the chromosomes. He finds in *Asterias* and *Hippopus* that the chromosomes do not arise out of the nucleolus, but the latter contribute nutritive substance to them. In the walking-stick-insect, *Aplopus*, he finds that half of the spermatozoa have eighteen, and half seventeen chromosomes, and the accessory chromosome is large and U-shaped and probably determines the female sex.

"Dr. Charles R. Stockard, of the Cornell Medical College, and Dr. Charles Zelemy, of Indiana University, found, working independently, that in the scyphomedusa *Cassiopeia samocohana* removing a greater number of the mouth-arms causes each and every arm to regenerate faster. Stockard finds also that although regeneration of each and

every arm is more rapid the greater the number of arms removed yet this regeneration is carried on at the expense of the normal body tissues which shrink while the arms grow, thus recalling the case of cancerous growths which, having more ability to absorb nutriment than the normal body tissues, grow at the expense of the body itself. Stockard finds also that the nearer the cut surface is to the center of the disk of the medusa the more rapid the regeneration. He finds that regeneration is somewhat retarded by a slight excess of NaCl, very much retarded by CaCl_2 , but not appreciably affected by Mg. A slight excess of KCl accelerates, and a strong excess retards regeneration. Zelensky, working upon the gulf-weed crab, *Portunus sayi*, finds that successive removals of appendages neither increase nor decrease the rate of regeneration of the successively removed part.

"An interesting series of observations were carried on by Dr. Stoddard in which he shows that the habits of the walking-stick-insect, *Aplopus*, accord perfectly with the general resemblance of the animal to a stick. He discovered that the males will mate with the cut-off terminal part of the female's abdomen if this be mounted upon a stick.

"Professor Jacob Reighard, of Michigan University, investigated the problem of 'warning coloration' in so far as it affects the brilliantly colored reef fishes and their enemies, and he shows conclusively that these brightly colored fishes are at once greedily devoured if they leave the shelter of the coral reefs. The commonest predatory fish of the Tortugas, the gray snapper, *Lutjanus griseus*, can, however, be taught to avoid a fish rendered artificially distasteful, and will remember its experience and still avoid the possible prey for at least twenty days after it has had the evil experience of attempting to devour such a fish. The coral-reef fishes are, therefore, not warningly colored, yet warning color could exist, but apparently it does not in nature; at least in so far as the reef fishes experimented with are concerned.

"Professor John B. Watson, of Johns Hopkins University, remained for three months upon Bird Key, Tortugas, studying the reactions of the noddy (*Anodus stolidus*) and sooty (*Sterna fuliginosa*) terns. This work was conducted under conditions of great inconvenience, for the temperature of the air under the bushes is commonly 123°F. at noon. Professor Watson found about 1,400 noddies, and 18,800 sooties nesting upon this little island not

a quarter of a mile wide. While the noddy is building its nest in the bushes early in May it is very shy, but as soon as the egg is laid its habits change and it will remain and defend the egg. If, however, an egg be artificially placed in an unfinished nest the habits of the birds at once change and they settle down upon the egg and defend it. They do not recognize their own eggs, and will sit upon hens' eggs, sooty terns' eggs, their own eggs painted red, green or black, or an artificially egg-shaped piece of magnesium sulphate. The sooty tern, however, will not usually accept colored, or strange-looking eggs. The noddies relieve each other on the nest at intervals of about two hours, the new-coming bird crowding the sitting mate off the nest.

"The sooty tern makes its nest upon the ground. It is greatly confused and may lay a new egg if the egg be moved twenty-two inches horizontally from the original place, but the egg may be raised or lowered many feet in a vertical direction and the bird alights upon it at once apparently undisturbed.

"The young birds of both species can be taught to go through a labyrinth for their food; and the old sooties can learn to go through a maze to their egg, or to open a cage to obtain access to the egg. Neither of these birds is in the habit of going more than about seventeen miles from the island for their supply of fish, yet when they were taken away in the holds of vessels and liberated at Key West, Havana and Cape Hatteras they returned to the island. In the case of the sooties, the return from Cape Hatteras to Bird Key was made in five days, the straight-line distance being 880 and the 'along-shore' route 1,081 statute miles. There are many other important observations recorded in Professor Watson's paper.

"The lecturer expressed regret that limitations of time prevented his presenting before the academy the results of other interesting studies which had been conducted by investigators at Tortugas, but would refer his audience to the papers of Jennings, Linton, Perkins and others who had published accounts of their researches at the laboratory."

The paper was discussed at considerable length by C. Hart Merriam, Austin H. Clark and T. S. Palmer, who heartily commended the work of the Tortugas laboratory, and referred to similar laboratories and their work in various parts of the world.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

The 661st meeting was held on February 27, 1909, Vice-president Abbot in the chair. The following papers were read:

The Relation between Sky Polarization and the General Atmospheric Absorption: Mr. H. H. KIMBALL.

Rayleigh has shown that sky polarization may be attributed to the presence of particles in the atmosphere whose diameters are small as compared with the wave-length of light, and the researches of Barus indicate that such particles must be "an integrant part of the air" and "could scarcely be separated from it except by filtration." We can not, therefore, expect marked fluctuations in the intensity of the polarized component of sky light.

On the other hand, the intensity of the unpolarized component will vary with the amount of light scattered by particles in the atmosphere whose diameters are large as compared with the wave-length of light, and with the amount reflected from the surface of the earth and from clouds.

Eliminating reflection from clouds, and allowing for variations in the reflection from the earth's surface, there remains as a variable factor the scattering of light by large particles in the atmosphere.

The intensity of the unpolarized component of sky light should, therefore, be a function of the number of such particles present, and consequently of the general absorption or diffusion of light by the atmosphere.

From observations with an Angström pyrheliometer and a Pickering polarimeter at the Central Office of the Weather Bureau, an empirical equation has been developed showing the relation between sky polarization and the general atmospheric absorption. By means of this equation polarimeter observations are now employed to check the computations of the value of the solar constant from readings of the pyrheliometer and the psychrometer by a method shown in Bulletin of the Mt. Weather Observatory, Pt. 4, Vol. 1. The results indicate a close relation between sky polarization and the general atmospheric absorption.

The Principles of Machines for Liquefying Gases:

Dr. EDGAR BUCKINGHAM.

The speaker discussed the principles involved in the action of simple liquefying machines as distinguished from cascade processes with one or more precooling stages. The total cold available depends only on the pressures between which

expansion takes place and the initial temperature of the gas; and with the ordinary type of liquefier is quite independent of the internal arrangement of the apparatus. The fraction of the gas that can be liquefied may be computed from its thermal and mechanical properties, if these are known; and the computed values agree very closely with those found by experiment. The increase in yield attainable by avoiding part of the dissipation within the liquefier may also be computed, and is very considerable. Methods for obtaining this improved yield were discussed briefly.

R. L. FARRIS,
Secretary

THE ACADEMY OF SCIENCE OF ST. LOUIS

The regular meeting was held on Monday, February 1, 1909, at the academy building, 3617 Olive Street, the program of the evening having been especially arranged in celebration of the centenary of the birth (February 2, 1809) of Dr. George Engelmann, one of the founders of the academy, and its first president. Standing not only among the leading medical practitioners of the last generation, Dr. Engelmann was also one of the foremost botanists of his day; for, during the many years of an active, useful life, most of which was spent in St. Louis, he found sufficient time, in the leisure hours of his practice, to devote to a series of most valuable scientific investigations. And, moreover, in addition to his professional and botanical labors, he was a zealous meteorological observer, keeping observations pertaining to atmospheric phenomena for over forty years.

Dr. Baumgarten opened the program of the evening with a very interesting paper, entitled "The Personality of Engelmann." And Dr. Baumgarten, having been a personal friend of the physician and botanist, was peculiarly well fitted to handle this subject, which he treated in a reminiscent way, making characterizations of a personal rather than mere biographical nature. This tribute of Dr. Baumgarten to the memory of his friend was one that bespoke only the most sincere friendship for Dr. Engelmann, and the highest appreciation of his character and achievements.

Professor H. A. Wheeler presented a paper on "Engelmann's Contributions to Geognosy." For Engelmann's reputation extended beyond the borders of his master work in botany and his devotion to local meteorology; although his influence in geognosy is perhaps due less to actual work done in that field than to the stimulation

he inspired in specialists of that department. In 1859 he published a paper that concerned itself with the elevation of St. Louis above sea level, which, aside from its general interest and scientific value, was especially important in that St. Louis was then the point upon which were based the computations for determining the altitudes of such places in the far west as were visited by the early exploring expeditions of Nicollet, Fremont, Owen and Emery. Engelmann, after a series of barometric observations in 1853, determined a directrix of 404.9 feet for the city of St. Louis—a figure which differed by only 7.3 feet from the later 412.7 feet mark as determined by precise leveling of government departments, and by only 2.2 feet from the original 410.5 of Nicollet which was made in 1841 by barometric determinations based upon data furnished by Engelmann himself. While the contributions of Engelmann seem slight when compared with his masterly work in botany and meteorology, they are, nevertheless, a valuable index of the breadth of the man, of the keen interest he took in the natural sciences, and of his mental caliber and scientific training.

Professor Nipher, of Washington University, in a paper, "Engelmann's Work in Meteorology," told how Engelmann began his meteorological observations when he first settled in St. Louis, and how he continued them for nearly fifty years. Dr. Nipher explained how this long series of observations enables us to determine the normal rainfall and temperature for St. Louis, and how they, in turn, are useful in fixing extremes of temperature and rainfall. In 1861, Engelmann published the results of his rainfall observations, which show that June is by far the month of greatest precipitation; and he pointed out that the June rise in the Mississippi is not due to the melting of snows in the mountains, but to heavy and wide-spread spring rains. The fact that Engelmann gave attention to the rate of rainfall is noteworthy because that is a quantity which must be considered in the design of bridges and other structures that are to carry flood water. After remarking that Engelmann made an early study of the differences of temperatures and humidity in the city and in Shaw's Garden (which was, he said, on an open prairie three miles from the city), Dr. Nipher concluded with the statements that Engelmann was continuously in cooperation with the weather service in charge of the Smithsonian Institution, and that in many ways his aid was solicited by government officials in charge of work in the far west.

Dr. Trelease, of the Missouri Botanical Garden, which possesses Engelmann's invaluable collections, concluded the program of the evening with a paper on "Engelmann as a Biologist." He showed a number of drawings which exhibited Engelmann's skill in picturing details of plant structure, among them those made for his thesis, which was published in 1832, as well as the large quarto volume in which his botanical publications were reprinted at the expense of Henry Shaw in 1887, under the editorial direction of the great botanist Asa Gray, of Harvard University. To these were joined specimens of the beautiful prairie flower named *Engelmannia* in his honor, and of the blue spruce of Colorado which also bears his name. Tersely epitomizing Engelmann's work, and analyzing the economy of time and directness of purpose which enabled him to accomplish in the leisure hours of a busy physician's life more than the average achievement of a botanist whose whole effort is directed to his specialty, Mr. Trelease closed by quoting from Engelmann's gifted biographer, Professor Sargent, of Harvard University, the prediction that "the western plains will still be bright with the yellow rays of *Engelmannia*, and that the splendid spruce will still cover with noble forests the highest slopes of the Rocky Mountains, recalling to men, as long as the study of botany will occupy their thought, the memory of a pure, upright, laborious and stimulating life."

At the conclusion of the memorial session, the members and guests of the Academy were invited to pass into another room, where were displayed a number of interesting objects connected with or commemorative of Engelmann's life and work. Under the guidance of Mr. H. C. Irish and Mr. Chas. H. Thompson, who explained the several objects, an interesting half hour was spent in the inspection of this exhibit, which included the manuscript and original sketches for Engelmann's thesis as well as the publication itself in a copy with partly colored plates; several volumes of his many thousands of unpublished notes and sketches; the simple dissecting microscope and the elaborate compound microscope made by Hachet; the jubilee medal struck by the academy in 1906, bearing Engelmann's portrait; an illustration of the Colorado Engelmann spruce; and specimens and original descriptions of the three genera of plants that have been dedicated to his memory in the name *Engelmannia*.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE PHYSICAL EXERCISE FROM THE STAND- POINT OF PHYSIOLOGY¹

MYTHOLOGISTS tell us that Æsculapius, the god of healing, was slain by a thunderbolt from Zeus because of complaints which had reached that deity that Æsculapius had become so skilful in his art that Hades was fast being depopulated. His tragic end, however, did not deter his courageous daughter, the goddess of health, from carrying on a vigorous propaganda; and, whatever the immediate result of her efforts, I am quite sure that her followers, the hygienists of the present day, are even more successful than are the doctors in delaying the day of our entrance into a future life. It has been many centuries since offerings to Hygeia were laid on her altars on the Grecian hills, but the aim of her cult has not changed. This aim, as I conceive it, is to bring to, and maintain at, its highest efficiency the organic machine. An unhealthy body is a pathological body, and any method is a legitimate hygienic method which tends to keep the body in a physiological status. Hygiene has been well called applied physiology.

What are the criteria of efficiency in a living body? One criterion is that the body's chemical processes shall proceed

¹ An address delivered in a symposium on "The Regulation of Physical Instruction in Schools and Colleges, from the Standpoint of Hygiene" before Section K (Physiology and Experimental Medicine) of the American Association for the Advancement of Science, Baltimore, December 29, 1908.

in a rapid, orderly and economical manner. Chittenden has taught us to beware of an excessive quantity of protein food, even though it may be questioned whether it is most economical to reduce our daily protein intake to as low a point as forty or fifty grams. Digestion should not be delayed. Oxygen starvation is most deleterious; and the two requisites for a sufficient intake of this essential element are, first, a sufficient supply outside the body and, secondly, an efficient respiratory mechanism. It can hardly be questioned that a rapid anabolism and a rapid katabolism are advantageous. The storage of much nutriment in the cells, in the form of glycogen or fat, is like putting one's money in a safe-deposit compartment, where it lies with no interest return to its owner. Food should be quickly utilized, either to form protoplasm or to yield energy. There is also reason to believe that intermediate katabolic products are harmful to the tissues, and that they should be quickly turned into the final excretory products and cast out. Thanks to the labors of Starling and others, we are now beginning to realize how far-reaching is the control of the various tissues by distinct chemical bodies, or hormones, produced in other tissues. Any interference with the production of hormones is obviously an obstacle to efficient action.

A second criterion of efficiency is that the body's physical, as distinct from its chemical, processes shall be adequate to the body's needs. Voluntary and involuntary muscles should possess size, toughness and contractile power sufficient for both ordinary and extraordinary demands. The heart should be able to resist a high blood pressure without detriment to its muscle fibers or valves. The capillary bed should be capacious. Vasomotor response should be ready. Respiratory organs should be

capable of quickly bringing in oxygen and quickly eliminating carbon dioxide. Osmotic exchange should be rapid. Secreting and excreting organs should be richly supplied with blood and lymph, and capable of quickly supplying their products. The amount of energy utilized in mechanical work should be as high as possible in proportion to the total amount of energy expended, and the work of Zuntz and others has shown that the former can be largely increased by training.

A third criterion of efficiency is accuracy and delicacy in the activity of the organs of special sense.

And a fourth criterion of efficiency is a skilful working central nervous system, playing its part effectively, whether with or without psychic accompaniments, and by means of excitation and inhibition exerting an adequate coordination and control of all the bodily processes.

From this summary of some of the factors that make up physiological efficiency I turn to one of the most important obstacles to its development. This is fatigue. Fatigue is a general biological phenomenon—wherever protoplasm exists, there fatigue is possible. Given everything else, it is fatigue that loses races and it is absence of fatigue that wins games. Fatigue occurs in both physical and psychical processes. It is normal, and yet it may easily overstep its ill-defined normal boundaries and become markedly pathological. While originating, it may be, in one tissue, it radiates to all others and touches the most remote. It manifests itself in striking physical phenomena, yet it is primarily a chemical one—a phenomenon of metabolism. It seems strange that, with all the centuries during which mankind has struggled against it, fatigue should still remain largely an unsolved problem. We seem to be on the

right track, but our progress seems immeasurably slow.

Not only logic but experiment tell us that fatigue has a twofold cause—diminution of substances essential to protoplasmic activity—and here oxygen and carbohydrate loom large—and accumulation of toxic products of katabolism, among which we reckon carbonic dioxide, paralactic acid and monopotassium phosphate.

That lack of oxygen is a potent factor seems probable from Hill's recent results, which seem to demonstrate the efficacy of pure oxygen taken into the lungs in quickly restoring one who is suffering extreme fatigue.

That lack of carbohydrate is in part responsible for fatigue seems evident from the abundant testimony, coming not only from daily human experience, but from many laboratory experiments, conducted by a great variety of methods, to the effect that sugar restores the working power of the fatigued neuro-muscular mechanism. In view of the complexity of the chemical changes involved in protoplasmic activity, it seems hardly possible that fatigue substances are limited to two end products of metabolism, carbonic dioxide and a phosphate of potassium, and one intermediate product, paralactic acid. Indeed, Weichardt has gone beyond this and claims to have found among the products of extreme muscular activity a specific toxin, which is analogous to bacterial toxins and capable of producing the symptoms of fatigue when injected into animals. And he further claims to have produced, by methods analogous to those employed with bacterial toxins, a specific antitoxin possessed of striking recuperative powers. These claims he supports by a large amount of experimental evidence. Without a repetition of his procedures—and I am unaware that any one has yet done this—it is difficult to express an opinion of value concerning the exist-

ence of his toxin and antitoxin. That he obtained from the tissues of his fatigued animals a poison of a high degree of toxicity seems undoubted; that this is capable of ready neutralization is less clear; and a sceptic may be inclined to be dubious of the specificity of Weichardt's products. The preparation of his antitoxin in this country is now protected by patents issued from Washington, and it is gratifying to feel that if it prove to be the long-sought antidote to fatigue, now commercialized it will come within the provisions of our pure food law.

Whether future research justifies Weichardt's claims or not, our conception of fatigue substances is bound, I think, to become extended. My study of the physiological actions of the three now recognized, and the similarity of these actions to those of β -oxybutyric acid, indol and skatol, have brought me to the conviction that we shall in the future probably find many intermediate products of metabolism which have the power of depressing protoplasm and putting it into the condition wherein it manifests the physical characteristics of fatigue. If this conviction proves to be well founded, we shall in the future recognize many fatigue substances. It may be convenient to regard some of these as normal and some as pathological, although I am inclined to interpret the difference between these two hypothetical groups as one of quantity rather than of kind.

We are still in the dark as to the respective parts played in the production of fatigue by its two so-called causes. Verworn's limitation of the term fatigue to the result of poisoning by toxic substances, and of the term exhaustion to the effects of the lack of substances essential to activity, is a convenient usage, but it should be borne in mind that both processes go hand in hand throughout the activity of the tissue, and even in what is popularly understood by

the term exhaustion there are evidences of the profound action of toxic substances.

Ever since Eukles, the progenitor of Hayes, Dorando and Longboat, ran and won the first Marathon race and gave his life for the privilege of announcing to the Athenians the victory of Miltiades, the phenomena of fatigue have been of profound interest. The cause of the death of Eukles can only be conjectured, but the laboratories, the gymnasia and the race tracks of modern days have given us many data of value. Without attempting to review completely the chemical, physical and psychical phenomena of fatigue, let us consider some of the most common and most striking of these. The universal characteristic of fatigued muscle is that its lifting power for a given stimulus is diminished. In the voluntary muscles of cold-blooded animals the process of relaxation is always slowed, often enormously, but this does not seem to occur with warm-blooded muscles. There seems no doubt that the muscles can endure, without detriment, great abuse from both of the factors engaged in the causation of fatigue. Any one who has observed the activity of an isolated and electrically stimulated muscle, from which the blood stream has been cut off and from which the accumulated fatigue substances are occasionally washed by a stream of oxygenated physiological salt solution, can not fail to be impressed by the long continuance of the muscle's activity and the enormous resistance to exhaustion which it shows, even when no food enters it. The muscle possesses within its cells material for performing an incredible amount of work. And no less resistance is shown by the trained muscle to the action of fatigue substances. Thurston estimates the average amount of a man's work per day as two million foot pounds. Carpenter calculated that in the last of the old-style six-day bicycle races, held in New York in

1898, the winner, Miller, performed on the first day more than fifteen million foot pounds of work, and on each of the six days an average of more than nine and one half million foot pounds, the latter being nearly five times man's daily average. Notwithstanding this great effort, Miller competed during the following month in a twenty-four hour race, and two months thereafter he won a second six-day race, breaking his previous record.

The results of fatiguing muscular effort are not confined to the muscles. The proper conditions for fatigue are, at the same time, presented to the nervous system, partly because of its own efforts and partly through the fatigue substances of muscular origin circulating in the blood. It is unfortunate that we know so little regarding the capability of fatigue of the nervous system. The one certain fact is that the nerve fiber can be fatigued only with difficulty. The former and still common idea that the brain and spinal cord are readily fatiguable and, in fact, are the first part of the individual to succumb in a contest, seems not to be justified by the experimental work of Hough, Storey, Woodworth, Joteyko, Kraepelin and others. In attempting last year to discover an efficient method of fatiguing the spinal cord by artificial stimulation, I could find no conclusive evidence that genuine fatigue had been accomplished. Sensations of fatigue are a resultant, chiefly, of the fatigue of tissues situated outside the brain and spinal cord. It seems not unreasonable, therefore, to believe that the central nervous system is highly resistant to fatigue. It is a noteworthy fact that it is the last part of the body to lose in weight in starvation—all the other tissues contribute of their substance that it may be preserved. In certain diseases, too, it is the last tissue to be attacked. When one considers the indispensable rôle which it plays in the drama

of the organism, and the fact that if it succumbs all will be confusion and the curtain must be rung down, the resistance of the central nervous system to fatigue would seem to be, like the known resistance of the nerve fiber, an essential fact of the animal economy. Yet nervous fatigue is an undoubted fact and is manifested by easily recognized physical and psychical phenomena. Fatigue from overwork is one of the common causes of neurasthenia.

The behavior of the heart in a fatiguing physical effort is always a matter of great interest. When an individual is called upon to perform intense and especially prolonged work, the heart is largely the key to the situation. There is no question but that the work of the heart is then enormously increased, partly because of the heightened arterial pressure, and partly because of the greater demands of the tissues for oxygen. McCurdy found that during a combination of the back and leg lift used in the physical examination of college students, the blood pressure, as measured in the upper arm by the sphygmomanometer, rose more than sixty per cent. After long-continued efforts, such as in the Marathon runs, the heart is always dilated, and often there are murmurs, indicative of valvular insufficiencies. It is not clear whether cardiac dilatation results solely from the excessive arterial and intraventricular pressure, or whether this undoubted cause is not reinforced by diminution of the tonus of the heart muscle due to the action of the fatigue substances. Indeed, the direct action of fatigue substances on heart and arteries is much in need of study. A sudden and acute dilatation may be a very serious matter, either endangering the life of the individual at the time or leaving permanent pathological effects. In a well-trained heart, however, there ought to be hypertrophy, as there is in a well-trained voluntary muscle, and it does

not appear that dilatation and hypertrophy are necessarily deleterious results of severe physical effort.

Besides cardiac dilatation, severe effort may produce other mechanical effects, such as hernias, the rupture of muscles and of blood vessels, and even the fracture of bones, but these must be looked upon as adventitious phenomena, possible but not probable sequelæ of excessive effort.

Both albumin and casts are very frequently found in the urine after excessive physical effort, usually so with Marathon runners. Why this occurs is not clear, but from the apparent causative connection of the toxins of infectious diseases with albuminuria, it may be questioned whether the albuminuria of fatigue may not be due to the action of fatigue substances on the renal cells. In this connection a recent discovery by Pearce and Sawyer is interesting. They found that the serum of dogs suffering from artificially produced nephritis, when injected into normal dogs, caused protein to appear in the urine. This discovery suggests the question whether there is a fatigue toxin which acts upon the kidneys as a nephrotoxin.

Excessive effort frequently brings on a high temperature, which may last for days afterward. It seems probable that this fatigue fever, like the fevers caused by bacterial toxins, is due to the action of toxic fatigue substances, but here again accurate study is wanting.

The metabolic changes in the body involved in fatiguing effort are much in need of investigation by modern methods. Our present knowledge of these changes need not here be discussed.

Fatiguing effort may thus result in a large variety of phenomena. Some of these have purely mechanical causes, but the majority of them may probably be traced primarily to the action, on the tissues, of the specific fatigue factors. The phenom-

ena are naturally more pronounced in those persons who are physically untrained. I shall not deal here in detail with the physiology of physical training, with its resulting hypertrophy of heart and voluntary muscles, and increase in strength, and in quickness and accuracy of movement. But I would emphasize one point, namely, that a most important element in training is the adaptation of the tissues to the toxic fatigue substances. Without this all the other benefits of training would avail nothing. It is well known that the body can adapt itself remarkably to even large quantities of poisonous drugs, when those are taken first in small and then in gradually increasing doses, extending over a long period. Exactly the same thing is found in physical training properly conducted. Moderate but increasing amounts of exercise, producing moderate but increasing amounts of fatigue substances, put the tissues into a state of tolerance or resistance, such that when the supreme effort is demanded of them, they do not succumb. He who wins is he who can best resist the poisons of fatigue.

What now is the teaching of physiology regarding physical exercises and physical contests?

In the first place, physiology teaches that the human body is capable of responding to enormous demands for physical effort. One's latent power in all of the three varieties of physical exercise—of strength, of speed and of endurance—is never realized except in emergencies, and then it often proves remarkable.

Secondly, physiology teaches the great value of proper training in increasing one's latent power. Yet training can easily defeat its object. As Darling rightly says:

The physiological effects of training, on the heart and kidneys in particular [and we might add, on the nervous system], may approach unpleasantly near to pathological conditions.

The physiological basis of overtraining is not altogether clear, but the fact of overtraining is undeniable.

Thirdly, physiology teaches that the fatigue of one tissue from over-use means the fatigue of all tissues. Extreme activity of the muscular system involves not only lessened muscular, but also lessened mental activity.

Fourthly, physiology bids us to beware of physical excess. According to Tissot there are three degrees of fatigue—slight fatigue or lassitude, which gives tone to the body; fatigue which irritates, excites and enervates; and fatigue which weakens; and he adds that the two latter degrees of fatigue should be absolutely avoided. With this view I can in general agree, and yet I would not here be an extremist. If I read aright the teachings of physiology, they are that physical exercise, carried to the point at which it produces extreme fatigue, and persisted in, can not fail to be harmful. The human body is, indeed, wonderfully resistant and capable of apparently complete recovery after a considerable degree of abuse. But it is not to be denied that extreme physical exertion is a debauch and, like any other debauch, leaves the individual mentally, morally and physically depleted. It is also not to be denied that the chances of continued well-being are enhanced if the debauch is never indulged in. No sharp line can be drawn between what is normal and what is pathological in fatigue. What is normal for one person may be pathological for another. Training should extend the boundaries of the normal. But it is safest to avoid those physical exercises that force the organism to the border line beyond which the abnormal lies. The one may pull his all in the tug of war or wield his oar in the four-mile race, or run his twenty-five Marathon miles. But it is the physically exceptional man who can do these things, and the physically average

man would best leave them to him who is exceptional. It is the physically average man who does the world's work, and if he becomes physically incapacitated, as he may easily become if he tries to become physically exceptional, not only the individual but the world suffers. It is not only the teaching of physiology, but it is the teaching of common sense to avoid physical excess. Common-sense hygiene should have its place in a liberal education. What a liberal education should do for the individual is so well put by Huxley that I am tempted to quote his words:

That man has had a liberal education who has been so trained in youth that his body is the ready servant of his will, and does with ease and pleasure all the work that, as a mechanism, it is capable of; whose intellect is a clear, cold, logic engine, with all its parts of equal strength, and in smooth working order; ready, like a steam engine, to be turned to any kind of work, and spin the gossamers as well as forge the anchors of the mind; whose mind is stored with a knowledge of the great and fundamental truths of nature and of the laws of her operations; one who, no stunted ascetic, is full of life and fire, but whose passions are trained to come to heel by a vigorous will, the servant of a tender conscience; who has learned to love all beauty, whether of nature or of art, to hate all villainess, and to respect others as himself.

Physiology tells me that this is the education which we should give to our youth.

COLUMBIA UNIVERSITY

*DEPARTMENTAL ORGANIZATION FOR THE
REGULATION OF PHYSICAL INSTRUCTION
IN SCHOOLS AND COLLEGES
FROM THE STANDPOINT OF
HYGIENE¹*

PHYSICAL instruction or physical education in the past has been handled largely

¹ An address delivered in a symposium on "The Regulation of Physical Instruction in Schools and Colleges, from the Standpoint of Hygiene," before Section K (Physiology and Experimental Medicine) of the American Association for the Advancement of Science, Baltimore, December 20, 1908.

from the standpoint of physical exercise. Gymnastics, or calisthenics, or games, or athletics have constituted the chief and often the only work done in physical instruction in many of our institutions. The word "gymnasium" has been and often is now, synonymous with the words "department of physical education." The objects of physical instruction have been predominantly those attainable through physical exercise. Many of our departments are even now interested mostly in bulk of muscle or in strength, speed, endurance and coordination; or in the development of a winning team or a star athlete; or in the perfection of bilateral symmetry and the production of grace of movement. And so we find the curriculum of the department including only, or chiefly, such individual and class work as may be handled from the standpoint of physical exercise. An anthropometric examination has been a common requirement because it has been assumed that by comparing the individual with the standard, his need for special developmental physical exercise would become apparent. He could then specialize more or less along certain lines of physical exercise and correct his deficiencies in form, symmetry, bulk or strength of muscle. Certain special medical data have been secured frequently because it was found that physical exercise might easily produce a serious effect upon unusually weak organs.

Further, the curriculum always provided some sort of work in physical exercise. This might be applied to the individual or to groups or classes. It consisted of mass drills or apparatus exercises, games, contests, swimming or athletic sports, or combinations of any two or more of these various phases of physical exercise. Special exercise was planned in many cases for those individuals who ap-

peared to need special or corrective development.

The instructors selected to handle departmental work have been selected with more or less special reference to the chief objects which the departments might have in view. These objects were in some cases predominantly anthropometric. They were rarely widely hygienic or medical and they were nearly always narrowly hygienic or purely gymnastic or athletic. For these reasons, the special preparation of the instructor in physical instruction has been occasionally medical, occasionally hygienic, rarely physiological, often anthropometric and usually gymnastic and athletic.

As a result of these limitations in departmental scope and staff equipment, the achievements of physical instruction have been restricted to some of the anatomical, physiological, hygienic and psychological effects of exercise; and because of these same limitations, the faults of physical instruction have been numerous and destructive. The instructors have not often been men of academic training or of scientific or of professional training. Such equipment was not asked for, as a rule, and often could not have been paid for had it been offered. With inadequately trained instructors on the one hand—I will not say poorly trained, because many of them were superbly trained for special phases of physical exercise, but not for physical instruction—and on the other hand with the departmental scope limited to one or more phases of physical exercise, it has naturally followed that physical instruction has been judged to be unacademic and that academic men have been reluctant to permit its academic advancement.

Furthermore, these conditions have made collegiate physical instruction appear to be synonymous with gymnastic

work, so that the Y. M. C. A. gymnasium, the church gymnasium, the factory gymnasium, the business man's gymnasium and the athletic club, are all classed popularly with the collegiate department and with each other. (It is not my purpose here to discuss relative merits and I must not be construed as deprecating the value of these gymnasiums, particularly those of the Young Men's Christian Association.)

Furthermore, this narrow departmental scope with its consequent limiting effect upon staff equipment, not only makes it impossible for the department to realize the broad health influences which we now believe belong to it, but it increases greatly the chances for physical injury to the individual student or pupil. Without a knowledge based upon a medical examination of the organic condition of the individual, it is impossible to plan his work wisely and safely. Without a sound knowledge of the physiology of exercise—and this includes the major part of all human physiology—it is unsafe to undertake to administer exercise to large groups of boys or men among whom unsuspected anatomical and consequent physiological weakness or abnormality may be present. Clearly, many of our teachers in physical instruction have not been adequately trained for even the relatively narrow field of physical exercise to which physical instruction has so long been confined. And it is no wonder that complaint has arisen from physician, physiologist, hygienist, educator and layman. It is no wonder that concrete examples of medical, hygienic and physiological error may be cited. It is no wonder that positive injury has been done to individuals. It is remarkable, rather, that so little injury has followed in the wake of these conditions.

On the other hand, there have always been thoughtful men in physical education who have held that the chief object

of their work was the development and maintenance of health. "A sound mind in a sound body"—this is an old battle cry—means a healthy mind in a healthy body. Some of our oldest directors have taken this position, though forced by circumstances and by training to rely almost wholly upon physical exercise for the accomplishment of their objects. These men have felt that physical instruction is bigger than physical exercise, and that physical exercise can not alone secure the desired effects on health. They have felt that physical instruction is concerned with physical health; that physical health is fundamental to normal physiological activity, whether that activity be expressed as locomotion, circulation, respiration, digestion, cerebration or any other organic function. We know that the physical health of the human body depends upon the health of the tissue cells of which the human body is composed. The health of these cells depends absolutely upon their nourishment, their exercise, their rest, the proper disposition of their excretions and the other products of their activities, and upon a reasonable freedom from the influence of disease-producing agents. The neglect of any one of the requisites may destroy the good effects of the proper observance of the others. And it follows that the physical health of the human body may be secured and conserved only by the observance of the several fundamental laws that operate in the production of health in the tissue cells. These laws are concerned with nutrition, excretion, exercise, rest, respiration, cleanliness and protection against disease. Their uniform observance means physical health. The neglect of any one law means failure in the effort to secure and conserve health, even though these other laws may have been properly observed. No man may expect good physical condition and

consequent health if he sleeps too little, or if he ruins his digestion and thus starves his tissues, or if he takes no exercise, or if he neglects his excretions, or breaks any other of these laws.

With these facts in mind a considerable number of men interested, feel that a department of physical instruction must teach the theory and develop the practise of these several fundamental laws of health in order to approximate the object for which such a department exists. It can not afford to neglect any one of these fundamental laws and it can not afford to overestimate any one of these laws.

We find evidences of this conception of the broad scope of physical instruction in many of our colleges. A year ago in the Society of College Directors of Physical Instruction, there were forty members, of whom thirty-two had academic or professional degrees. These thirty-two men have sixty-one degrees. Less than a year ago at the second congress of the American School Hygiene Association, Meylan, of Columbia University, reported that thirty-one out of thirty-two college departments of physical instruction which replied to his questionnaire were giving courses in hygiene. This means that some of these departments are in the hands of men with academic sympathies, men who are trained medical experts, men who are experienced hygienists; and that these men combine this equipment with that of a practical experience in the technical procedures of gymnasium work. The departments under these men are being organized somewhat as follows: First, all students or pupils are in many places required to undergo a medical examination. The tendency of the modern college and high school is to require this examination of all individuals whether they are planning to go into athletic or gymnastic work or not. In most colleges opportunities for

medical consultation are provided. In some colleges and high schools, frequent medical inspections are required. On the basis of these examinations, inspections and consultations, the school life and departmental activities of the individual are regulated. This influence goes so far in some instances as to debar the individual from attendance because of his physical condition. In any event, his physical exercise is planned in conformity with these medical findings, so that the possibility of injury to weak organs through excess exercise influences is greatly minimized.

Second: A hygienic and sanitary supervision is exercised in some institutions. This supervision is closely related to the medical supervision. In fact, they can not be separated entirely. This combined supervision, medical and hygienic, regulates the physical exercise applied in the department. It selects and grades the drills and exercises in the various courses with reference to desirable physiological, anatomical and mental effect. It plans the special work for the special cases with special reference to the conditions that are found on medical examination. Further, it enforces a practical application of hygiene and sanitation throughout the department and often throughout the other departments of the high school or college. Such a supervision can and does enforce bodily cleanliness in the exercising hall; enforces clean gymnasium suits and towels; and enforces regulations relative to spitting and other nuisances in locker rooms, hallways and corridors; and regulates the sanitation of the toilet rooms, shower baths, swimming pool and so on. Pupils and students whose personal hygiene is obnoxious may be required either to improve their hygiene or leave the institution. This influence may easily extend to secure an improvement of the student's home surroundings, because his own

hygiene can hardly surpass that of his environment.

It can be easily seen that this medical and hygienic supervision secures: first, protection from contagion; second, discovery of and expert advice concerning remediable physical defects; third, regulation of exercise in conformity with the organic limitations of the individual; fourth, the application of the laws of hygiene and sanitation to the individual and his institutional surroundings; fifth, a habituation to hygienic practises which is likely to influence the individual and through him his surroundings for the remainder of his existence.

A third phase of this modern departmental organization provides for instruction concerning the simple fundamental laws of human health. Personal hygiene, general hygiene and sanitation are being taught in these departments. Courses are given on such subjects as "Ways and Means of Securing and Conserving Health," "The Influence of Common Abnormalities and Habits of Health," "The Causes of Diseases," "Carriers of Disease," "Defenses against Diseases" and "The Nature of Some Common Diseases." These courses teach some of the main facts of nutrition, exercise, rest, excretion, bathing and disease, so that young men may carry away an intelligent policy of personal health control.

The fourth division of departmental organization is that which provides instruction in the various phases of physical exercise, including mass drills, apparatus exercises, swimming, and indoor and out-of-door games, sports and play. This work is being carefully graded. It is taught with direct reference to its influence on the health and character of the individual and therefore with a close adherence to the laws of physiology, hygiene, psychology and medicine as we now understand them.

Mass of muscles, strength, speed, endurance and coordination are secured incidentally. They are indeed often desirable, but are not the main objects of such work. These various phases of physical exercise are planned with reference to their primary influence on tissue health and their inevitable secondary influence on functional efficiency, such as voluntary muscular contraction, circulation, respiration, digestion, assimilation and cerebration. They do their heavy share of the work necessary in order to turn out men of health, men of courage, men of self-reliance, men of self-respect, men who think on their feet and not on their thoughts, and men who have learned the value of combined effort and the subordination of the individual interest to that of the group.

As an example of departmental organization in these four phases of physical instruction, permit me to cite a department that has come under my close observation. This department is in a college in which the combined academic and collegiate attendance reaches about four thousand. The department of physical instruction there is given a medical and hygienic supervision over the entire student body. A medical examination is required of all entering academic and collegiate students. The medical inspections are required each half year of all academic pupils and of all freshmen and sophomores. Medical consultations are open to all students on their own volition or on request of their instructors. All candidates for athletic teams undergo a special medical examination before admission to competition or training. Upon recommendation from the department, all students whose physical condition is a menace to their companions are debarred from attendance until the complaint is removed. All students whose physical condition requires it, are given special exercise during the terms in which they are

required to attend classes in the department.

A special hygienic and sanitary supervision is exercised over the students in the department and over the departmental building and all of its subdivisions.

Instruction in hygiene is given in six courses to each of the six classes that are required to take work in the department. These courses cover "The Ways and Means of Securing and Conserving Health," first term; "The Influence of Certain Abnormalities on Health," second term; "Some of the Causes of Disease," third term; "The Carriers of Disease," fourth term; "Defenses against Disease," fifth term; and "The Nature of Some Common Diseases," sixth term.

Instruction in physical exercise is given to these six classes. The mass drills are carefully graded throughout the six terms. The apparatus work is graded during the last four terms required in the department, that is, during the freshman and sophomore years. Graded requirements in swimming are in operation in each of the courses in the department and are classified under "Apparatus Work." No out-of-door work is provided, so that this seriously important phase of exercise is neglected. Certain games are taught in the department.

A typical class hour is divided as follows: first period, floor talk on health; second period, mass drill; third period, apparatus work.

Written examinations and practical tests are required every month and final written and practical examinations are applied each term. The records of these examinations are filed with those from the other departments with the secretary of the faculty as term and final examination marks; credits are given for the work.

Let me summarize the main points of my paper as follows: First: Physical instruction has been handled largely from the

standpoint of physical exercise; this standpoint has limited the scope of the department to the possibilities that lie within the range of physical exercise. It has restricted the preparation required of teachers of physical instruction to those subjects or experiences bearing on some one or more phases of physical exercise, and it has made possible and deserved many criticisms because of its unacademic character and its opportunities for the commission of injury to individuals.

Second: There have always been a few directors of physical instruction who feel that their field of work is larger than that of physical exercise, and that it is concerned with human health.

Third: Physical instruction is now being handled more and more from the standpoint of human health. This point of view broadens the scope of the department so that it includes medical, sanitary and hygienic supervision and instruction concerning the simple fundamental laws of health and the various phases of physical exercise. This broader departmental scope necessitates the employment of experts upon the staff whose special training has fitted them for medical, hygienic and sanitary supervision and instruction as for instruction in the various and important phases of gymnasium and athletic work.

In conclusion, gentlemen, permit me to state that we who are interested in these tendencies in physical instruction believe they are tendencies in the right direction. We believe that our professional and pedagogical aim has in view the achievement and conservation of human health through the regulation of physical instruction from the standpoint of hygiene. We believe that this broad field belongs logically to us. We believe that if we can develop and conserve health in human beings, and teach them how to exercise an intelligent policy of personal health control, we shall

have utilized whatever special scientific, medical, hygienic and pedagogical training we may have, for the best interests of humanity of which we are a part and of the world in which we live.

THOMAS A. STOREY

COLLEGE OF THE CITY OF NEW YORK

THE CARNEGIE FOUNDATION FOR THE ADVANCEMENT OF TEACHING

THE annual reports of President Eliot to the corporation of Harvard University have in certain respects been the most interesting educational documents of past years; their place will now be taken by the reports of President Pritchett of the Carnegie Foundation. In these reports and in the intervening bulletins, there are not only given lucid and complete accounts of the activities of an institution of vast importance for higher education, but also careful studies of the educational system of the country. In this respect the foundation sets an example to the General Education Board, which keeps for its private use the information that it collects, and does not even publish the financial statements that should be required by law from every corporation, and first of all from those exempted from taxation.

President Pritchett's third annual report, which covers the year ending September 30, 1908, shows that the new grants made during the year amounted to \$113,785. The grants in force amounted to \$303,505, an increase of \$101,360 over the preceding year. Should this increase continue for two further years, the income of the foundation would be exhausted. The retiring allowances in force were: On basis of age, 86; on basis of length of service, 81; for disability, 15; to widows of professors, 23. The average age of those retired for length of service is 65.7 years, so that it would appear that more than half of them are entitled to retirement for age. The aver-

age value of the retiring allowances is \$2,522.50. The institutions drawing the largest sums are: Yale, \$25,195; Cornell, \$16,570; Harvard, \$16,305; Tulane, \$14,365; Columbia, \$14,055; Stevens, \$11,075.

Valuable data are given in the report in regard to institutions on the accepted list and the state universities, together with a discussion of political interference in tax-supported institutions with special reference to the University of Oklahoma. Other topics treated are: the exchange of teachers between Prussia and the United States; uniformity in financial reports; teachers' insurance; college requirements for admission; special students; amount of instruction given by teachers; professional education; denominational education.

The foundation adopted during the year two new policies of great importance—one the admission of tax-supported institutions for the cost of which Mr. Carnegie has undertaken to give \$5,000,000, the other the provision that a widow shall receive half the pension to which her husband would have been entitled.

There is no valid reason why the states should not accept a gift from Mr. Carnegie for their universities. In so far as the money came originally from the people, and especially from the agricultural regions of the central and western states, through the workings of the tariff, this was imposed by the representatives of the states, and the best use of the money is to return it to those from whom it was taken. Nor is the fact that the fund is in the form of bonds of the United States Steel Corporation significant. All our universities hold bonds of railway and other corporations whose activities have not always been beyond reproach.

The real questions are whether a centralized pension fund is for the advantage of our universities, and, if so, whether a fund can be provided sufficiently large for

the purpose. The writer dissents from most of his colleagues in doubting the desirability of a uniform and centrally administered pension fund. I have always been prejudiced against annuities and those who buy annuities; it is distasteful to me to be thrust by force of circumstance into this class. The president of one of our leading universities has stated in a report to the trustees that the annual value of the pension to a professor in middle life is \$1,200. I should prefer to have this increase to my salary now when I have children to educate; or, if it could be saved, to have it as capital to be used for such purposes as may be desirable and to be bequeathed to my family. The withholding of part of a professor's salary to be paid ultimately after good behavior in the form of an annuity will tend to increase the autocracy of university administration and to limit not only the freedom of action but also the freedom of speech of the professor. It will also limit the freedom of action of the administration, for a professor can not be dropped honorably when part of his salary has been reserved for a pension. It seems from the decision of the courts in the case of Professor Capps against the University of Chicago that this can not be done legally, and there will probably arise complications which have not been fully foreseen.

It is not intended to imply that the office of the professor should be subject to the commercial law of supply and demand. On the contrary, he should have life tenure, only forfeited by the violation on his part of the conditions implied in accepting the office. It would be intolerable if a professor could be dismissed simply because the president thinks that he might obtain a more acceptable man in his place for the same or a smaller salary. The professor is appointed at the average age of nearly forty years and is likely to remain what he

then is; if an unwise appointment has been made, the institution should accept the responsibility.

Permanent tenure of office doubtless implies a continuation of salary or a pension in case the professor can no longer serve to advantage; and this leaves the difficulty resulting from paying a professor less than he is worth in middle life in order that he may receive more than he is worth in old age. Obviously we must face this situation; but it is emphasized and made worse by the establishment of a uniform and centralized system of pensions. It can be most conveniently met if we are sufficiently optimistic to assume that on the average the services of professors over sixty-five years of age are worth to their institutions and to the community the salaries that had previously been paid. A professor at this age may become a less efficient teacher in professional and required courses, though this is not always the case. It is, however, by no means certain that he is, on the average, a less desirable teacher in advanced and elective courses; or that his scholarship, experience, judgment and poise are not of the utmost advantage to the university. A man of this age may not have new ideas; but his research work and productive scholarship are likely to continue and to be of greater value to the world than the salary he is paid.

The teachers who have had the greatest influence on the writer are Professor March, of Lafayette College, and Professor Wundt, of Leipzig. Professor March ceased to teach recently at the age of over eighty years and Professor Wundt continues to lecture regularly at the age of seventy-five years. It would have been a serious loss if these great men had ceased to teach at the age of sixty or sixty-five. If I were now beginning the study of psychology, I should wish to spend a year under Professor Wundt at

Leipzig and a year under Professor James at Harvard. I should be able to work under Professor Wundt, but should find that Professor James had been retired on a Carnegie pension in the fullness of intellectual vigor. If Mr. Angell can to advantage serve as president of Michigan to the age of eighty and Mr. Eliot can serve as president of Harvard to the age of seventy-five and still retain the chairmanship of the trustees of the Carnegie Foundation, we have evidence that a dead line can not be drawn at sixty-five.

The institutions accepting the terms of the Carnegie Foundation for pensions on the basis of age must make retirement on a pension at sixty-five mandatory, or else they must make it a matter of arrangement between the administration and the professor. Either alternative is unfortunate. If the retirement is mandatory, the institution will lose men whom it can not afford to lose, and professors will be retired who are competent and anxious to continue their work. It will be a poor reward in the academic career to cut men off from the service of their lives and pay them part salary, when in other professions at that age they would probably have continued to be leaders and to have had an income at least twice as large as twenty years before. If the retirement is only permissive an institution might gain temporarily by retiring its less efficient men; but this would be only a mitigated form of the policy of dismissing professors whenever their places can be filled at less cost. Every institution could improve for a time its faculties by dismissing twenty per cent. of its professors; but such an undertaking would in the end be disastrous to the institution and to higher education. If only incompetent professors and those not in favor with the administration are retired at sixty-five, the pension will be far from an honor and by no means a worthy close

to an academic career. It will frighten able men from it at the outset, and tempt them to desert it when they can.

It may give a sense of security to be assured of a pension in old age; but when the time comes the reduced salary will cause difficulty to those not having independent means. There will be a tendency for the professor to engage in some form of money-making and to begin early in his career. An eminent man of science has written to me that since he had been retired on a Carnegie pension he could no longer contribute to a scientific journal, as he had to earn a living for his family by writing fiction. The community and the world are largely dependent on the university professor for the advancement of science and scholarship and for the maintenance of the best ideals, and those great services are not paid for directly. They can only be assured by attracting the best men to university chairs and then setting them free to do their work with no interference and no fear of dismissal even on half salary.

In my opinion the Carnegie Foundation would have been most wisely administered if it had agreed to give to every institution that had adopted or would adopt a half-salary pension after the age of sixty or sixty-five an endowment sufficient to defray the remaining half of the salary, so that the professor would be paid his regular salary for life. He could then retire from the teaching for which he was not fit, but could continue to give his services to his institution and to his science. Or if the allowance had been paid by the foundation directly to the professor without regard to whether or not he continued his teaching, then he could give to his institution so much service as he might render to advantage and in turn receive so much salary as he might earn.

But the trustees of the Carnegie Foun-

dation are presidents, not professors, and the money is to be divided in the main so as to relieve the financial straits of the institutions, not to improve the status of the professors. The professors in those institutions which already had a pension system do not gain financially as far as the old-age scheme is concerned and lose in certain ways; whereas the institution gains the amount it had contracted to pay in pensions. The professor as well as the president is pleased that the university has added resources; but they do not differ from any other unrestricted endowment.

The conditions are different in the case of institutions which did not have a pension system. Here too it is chiefly the institution which gains, for it was bound in honor to provide for its disabled professors, and it will hereafter pay smaller or less increased salaries in view of the pensions.¹ But the presidents and professors have an assurance that they did not have and will have annuities that they did not earn or only partly earned. The advisability of having made the pensions retroactive in this way is questionable. Gifts may be at the same time acceptable and demoralizing. When Tulane University raises nominally its entrance requirements beyond what can be met by the high schools of Louisiana in order that it may be accepted by the foun-

¹ It is not admitted by the officers of the foundation that pensions will tend to prevent increase of salaries; but this appears to be an inevitable result of economic law. In seeking recruits for the army and navy the government states that the small wages are compensated for by the pensions, and one of the state universities has urged that if the legislature does not accept the pensions from the foundation, it will be necessary to pay higher salaries in order to retain its professors. A pension system may or may not improve educational efficiency, and it may or may not improve the general conditions of the academic career; it will not improve permanently the financial status of the professor.

dation, we are not surprised to find that it draws annually \$14,365, and when the Central University of Kentucky cuts itself off nominally from its denominational control in order that it may be accepted, we are not surprised to find that three of its eleven professors are immediately placed on the foundation.

It would, I believe, have been far better if the foundation had undertaken to hand over to each institution that had adopted or would adopt a pension system an endowment from the income of which the professors' salaries could have been maintained for life. Even if it were decided to give a pension smaller than the salary, the endowment might with equal advantage be made once for all. The foundation could in this case take up one institution after another and from its income award a fund sufficient to endow a pension scheme in each. Under these circumstances, the income would never be completely tied up, but could always be used in the way most likely to promote the advancement of teaching. The same plan might with great advantage be pursued by the Carnegie Institution of Washington. If instead of attempting to administer from Washington scientific institutions in all parts of the country, it would found and partly endow such institutions, and then leave them to local control and support, the money would go much farther and the dangers of a bureaucracy would be avoided.

The drawbacks of a centralized pension system may be illustrated by an example. A professor has reached the age limit with a salary of \$4,000. He prefers to continue his regular teaching and research and can do so competently. If the institution had to continue his salary, it would have no inclination to relieve him of his duties, nor would it care to do so if it had to pay a pension of \$2,400, for in this case the \$1,600 released would not suffice for the

salary of a new professor. But if the payment of the professor's pension can be put off on the Carnegie Foundation, then the president will reflect that he can obtain a new man about equally competent for \$3,000. He will thus save \$1,000, and the institution will still have credit for the work of the retired professor; the students he attracts; the indirect teaching that a man engaged in research at the university can not fail to do; his valuable judgment and counsel. The institution saves \$1,600 and gets \$2,400 more than it could not get in any other way. At first sight it may seem that no one suffers except the dismissed professor; but in the end it will be found that the institution and higher education also suffer.

The risks of the system for the professor are increased by the scheme of retirement after twenty-five years of service. Sixteen of the most efficient professors in Harvard University and fifteen in Columbia University are now liable to compulsory retirement apart from age; and owing to the great growth of these universities within the past twenty years, the number of men in this class will increase rapidly. These institutions could take from the Carnegie Foundation about \$75,000 a year now by retiring these men and probably two or three times as much a few years hence. If the emeritus professors maintained their interest in the institution and continued their research work, the university would apparently lose but little in return for the great financial gain. But the professors would suffer, and ultimately the whole academic life would be demoralized.

The reasons leading to the adoption of retirement after twenty-five years of service are obscure to me, unless it is intended to relieve institutions of men whom they do not want to keep. Some few professors having independent means or outside employment may like to retire on half salary;

but these are exactly those who do not need pensions. Any who may be disabled after twenty-five years of service and before reaching the age-limit gain; they are, however, but few and should be otherwise provided for. It appears to be a mistake to hold up retirement from the life-work of a professor as a prize or reward. The usual professor can not afford to retire unless he engages in money-making, and the plan will thus lead to commercialism and the discouragement of research. He is permitted by the rules to do anything except teach—that for which he should be most competent and that which he should most enjoy. Research work and advanced teaching can be carried on far better in conjunction than divorced. In order to reward a professor after long years of service, he should be relieved, not of half of his salary and the privilege of teaching, but of so much routine instruction and administration as interfere with his research. This is now done in our better universities; professors of distinction who wish to devote themselves mainly to advanced students and research work are encouraged to do so.

There is a minor difficulty in the way of retirement—whether it is to be a reward or a punishment—after twenty-five years of service as professor in that it is impossible to date fairly the beginning of such service. In every university some professors between the ages of fifty and sixty-five will be liable to retirement on the basis of age and others not, but there will be no significant difference in the work that has been accomplished for education and scholarship by the two classes. According to the circumstances of the case, it will be an advantage or a risk to have been given the title of professor at an early age in a small institution. It may on the whole be regarded as fortunate that the Carnegie Foundation has not the means to continue these annuities for length of service. They

will, I fear, tend to demoralize both the “humble and ill-compensated” professor and the “conspicuous” and much-tempted president.

A very useful service that the Carnegie Foundation could perform for the professor and for academic life would be some form of pension for disability, as this can not be purchased. Another useful service would be the pensioning of widows and minor children. Personally, I should prefer to let the professor purchase voluntarily at cost the disability annuity and the life insurance; but I am instinctively an extreme individualist. Certainly the pensioning of the widows of professors entitled to pensions by statute instead of by favor is a notable advance made by the foundation last year. The enforced pensioning of widows is even more socialistic than the enforced purchase of annuities; for ultimately the unmarried professors will be compelled to pay part of the premiums on behalf of their more fortunate colleagues. But it may be that people who bring up children deserve more from the world; certainly those who have only the annual income which they earn for those dependent on them should insure their lives, and perhaps they should be compelled to do so. The weakness of the system of the Carnegie Foundation is that it applies only where it is least needed. It is the instructor or junior professor with young children, having had no chance to save, who finds it hard to pay an insurance premium and sometimes neglects it.

It is not clear to the writer how it was estimated that a fund of five million dollars would provide pensions for the state universities and colleges. The demands on the foundation will depend on whether retirement is mandatory or whether it ordinarily follows only on disablement. At Harvard University there are at present seven professors on the retired list, two widows re-

ceive pensions, and the cost to the foundation is \$16,305. There are twenty-eight other professors now eligible to receive allowances. Should they be compelled to retire or wish to do so, the total charge of Harvard University on the foundation would be about \$75,000.

Even with a stationary number of professors and stationary salaries, there are two circumstances which will add greatly to the cost of the system. One of these is the "age distribution of the population," a factor which the trustees of the foundation may not have considered, as it appears to have been completely overlooked by both advocates and opponents of the old-age pensions in Great Britain. The population of that country, through a high birth rate from 1850 to 1900, has increased greatly since the middle of the last century, and the people form a youthful population. There are probably two to three times as many people over seventy years of age per thousand of the population in France, with its stationary population, as in Great Britain. The British chancellor of the exchequer will be awakened to the apparently unexpected circumstance that the number of those entitled to pensions from the government will be doubled or tripled apart from any increase in population. Similar conditions obtain in our universities which have more than doubled the number of their professors in the course of the past twenty or thirty years. Nearly all those appointed to professorships were young and are now growing old together. In twenty-five years the relative number of professors over sixty-five will probably be doubled or tripled.²

The other circumstance that will increase the demands on the funds of the foundation

²In the faculty of pure science of Columbia University there are fifty-two professors, the ages of forty-seven of whom are given in "American Men of Science." The distribution is:

is the pensioning of widows. Professors are nearly or quite as likely as their widows, and the expectation of life of their widows will be nearly or quite as great as their own when eligible for pensions. Thus the cost of the widows' pensions will ultimately be nearly or quite one fourth the cost of the annuities. It is further to be noted that all widows will receive pensions, even though a considerable proportion of those entitled to annuities do not draw them.

It consequently appears that with the same number of professors and the same salaries as at present, Harvard University would after a few years be able to take from the foundation at least \$150,000 a year in annuities and at least \$35,000 in widows' pensions. How much would actually be taken for annuities would, of course, depend on whether or not retirement were mandatory or generally adopted.

The number of professors will not remain stationary, nor will salaries remain stationary. Harvard has about doubled in size in the past twenty years and quadrupled in size in the past forty years. Even should this rate of growth not continue at Harvard, it will, I believe, be maintained on the average and will be exceeded in the state universities. Harvard and Columbia may in forty years have four

Age	Number
30-35.....	4
35-40.....	8
40-45.....	12
45-50.....	9
50-55.....	9
55-60.....	1
60-65.....	3
65-70.....	0
70-75.....	1

The median expectation of life of these men is at least twenty-five years, and we may expect that more than one half of the thirty-four now between forty and sixty-five will still be living twenty-five years hence. In the place of one man over sixty-five years of age and eligible to be pensioned for age (there is now none retired on a pension), there will be seventeen.

times as many professors as they now have; Michigan, Illinois, Wisconsin and the other state universities will almost surely have four times as many. It is a modest hope that salaries will increase fifty per cent. The cost in a great university of a pension system such as that of the Carnegie Foundation, if all retire who are eligible, may forty years hence be expected to be in the neighborhood of one million dollars a year. If at that time trust funds bring 3 per cent. interest, it will require \$30,000,000 to endow a pension system for a single university; and there will probably be not fewer than twenty such with a hundred others tending to become such.

Forty years hence some two billion dollars may be required to endow completely a centralized pension scheme for North America such as that of the Carnegie Foundation. Nor is this too long to look ahead. Young men of twenty-five, now entering the academic career and accepting smaller salaries in view of a pension at sixty-five, will not be honorably treated should it be withdrawn. Indeed they can possibly recover the pension at law.

The figures given here may seem somewhat appalling; but they are really not so. If pensions are only paid for disability at any period in the lives of university teachers and to their widows and minor orphans—I believe that no other kinds of pensions are desirable—the cost would be much less. It would represent a capital far beyond the possibility of private endowment, but would be a sum not considerable in comparison with the wealth of the country. Twenty times the amount could to advantage be saved each year by a reasonable reduction in the expenditure for alcoholic drinks. The economic gain to the nation and to the world from the research work of university professors far exceeds their salaries and their pensions, even though no account be taken of the value of their

teaching or of their contribution to ideal ends. The more scientific men the world supports, the richer will it become, as well as the better. But the nation, the states and the cities must maintain their universities.

J. McKEEN CATTELL

RECENT STEPS IN THE CONSERVATION MOVEMENT

SOON after the assembling of the Sixty-first Congress in extraordinary session, the Senate created a committee on the conservation of our natural resources, comprising Senators Dixon (chairman), Clark, of Wyoming, Beveridge, Dolliver, Dillingham, Heyburn, Dick and Briggs, of the majority, with Senators Guggenheim, Jones, Newlands, Overman, Davis, Bankhead and Smith, of South Carolina, of the minority. Of this committee, Senators Dixon, Newlands, Dolliver, Bankhead, Beveridge and Overman are members of the National Conservation Commission.

While the Rivers and Harbors Act passed by the Sixtieth Congress made but limited appropriations chiefly for continuation of current work, the provisions for surveys affecting new projects was exceptionally, indeed unprecedentedly, liberal; and specific provision was made for a legislative waterways commission, empowered to carry forward the framing of plans for waterway improvement, and for requisite investigations in this and other countries. This commission has now been organized by the Sixty-first Congress; it comprises Senators Burton (chairman), Gallinger (vice-chairman), Piles, Smith, of Michigan, Simmons and Clarke, of Arkansas, with Representatives Alexander, Lorimer, Stevens, Wanger, Sparkman and Moon, of Tennessee. Senator Burton was for a number of years chairman of the Rivers and Harbors Committee, and is chairman of the Section of Waters of the National Conservation Commission, corresponding to the Inland Waterways Commission.

On March 24 the four national engineering societies (American Society of Civil Engineers, American Institute of Mining Engi-

neers, American Society of Mechanical Engineers and American Institute of Electrical Engineers) held a joint meeting in the Engineering Societies Building in New York City devoted to the conservation of our natural resources. In the absence (due to illness) of Onward Bates, president of the senior society, Dr. James Douglas, president of the Institute of Mining Engineers, presided. Addresses were delivered on behalf of the four organizations on "The Conservation of Water," by John R. Freeman; on "The Conservation of our Natural Resources by Legislation," by Dr. R. W. Raymond; on "The Waste of our Natural Resources by Fire," by Charles Whiting Baker, and on "Electricity and the Conservation of Energy," by Lewis B. Stillwell. In addition to the set addresses, Dr. Douglas outlined in general terms the development of the conservation idea and the important part played by the engineering societies in directing attention to the nature and extent of resources and to the enormous wastes in utilizing them; while John Hays Hammond read a communication addressed to the meeting by President Taft commending its purposes and reiterating his deep interest in the natural resources and their conservation. The meeting was especially notable as marking a definite policy of cooperation on the part of the engineering interests of the country and of the four great national organizations in which these interests find expression. The attendance was large, including a number of engineers and guests from other cities.

W J McGEE

SCIENCE BY CABLE

WE reproduce the following cablegrams to the daily papers which, in so far as they are correct, are certainly of interest:

London, March 26.—Addressing the Chemical Society yesterday afternoon, Sir William Ramsey announced that he had succeeded in transmuting four different substances into carbon; namely, zirconium, thorium, hydro-lutrasilic acid and bismuth. Experiments with silver nitrate, with the object of transforming silver in the same manner as copper is transformed into lithium, gave negative results.

Paris, March 23.—The astronomer *Paul Gautier* announced before the Academy of Sciences last night that he had discovered two new planets situated beyond Neptune, which is the outermost known planet of the solar system. M. Gaillot stated that he had used the methods which had enabled Le-verrier by mathematical calculation to assign to Neptune a position within the boundaries of a certain region, which permitted of its discovery in 1846. M. Gaillot estimated that one of the planets was forty-five times and the other sixty times the distance of the earth from the sun, or 4,185,000,000 and 5,580,000,000 miles respectively. The planet Neptune it is estimated is 2,260,000,000 miles from the sun.

Berlin, March 26.—Professor Richard Gress, of the Berlin University Eye Hospital, announced the discovery of the germ of trachoma. The finding of this germ resulted from experiments with apes conducted with funds supplied by the German government.

SCIENTIFIC NOTES AND NEWS

THE return of Lieutenant Ernest H. Shackleton, of the British navy, from his Antarctic explorations and his remarkable results in reaching a point within a hundred miles of the South Pole, in reaching the magnetic pole, in ascending Mt. Erebus and in making discoveries of importance in many directions, were announced in the daily papers of March 24.

DR. E. PFLÜGER, professor of physiology at Bonn, has been awarded the gold medal for art and science by the German emperor, on the occasion of the celebration of the fiftieth anniversary of his appointment to the full professorship.

DR. ALBRECHT PENCK, professor of geography at Berlin, has been elected an honorary member of the Geographical Society at Rome.

MR. B. E. DAHLGREN, formerly modeler at the American Museum of Natural History, New York, has been appointed modeler to the botanical department of the Field Museum of Natural History, Chicago. Mr. Dahlgren is now in Jamaica making studies for the reproduction of a series of tropical plants representative of structural characteristics as well as economic use.

THE *Naturwissenschaftliche Rundschau* announces that Dr. J. Königsberger, associate professor of theoretical physics at Freiberg, has accepted a position in the Geophysical Laboratory of the Carnegie Institution of Washington.

DR. P. RENNER has been appointed curator of the cryptogamic herbarium at Munich.

RECENT foreign visitors at the Bureau of Plant Industry, Washington, have been Professor Vittorio Peglion, of the University of Bologna, Italy; Sr. Don Romulo Escobar, president of the Agricultural College of Chihuahua, Mexico; Mr. Joseph A. Rosen, chief of the Agricultural Bureau of the Governmental Zemstvo of Ekaterinoslov, Russia.

PROFESSOR PAUL HANUS, of Harvard University, was elected president of the National Society of College Teachers of Education, at the recent annual meeting in Chicago.

DR. JAN BOSSCHA, professor of physics at the Delft Technical School and secretary of the Dutch Academy of Sciences, has retired from active service.

DR. HAVEN METCALF, of the Bureau of Plant Industry, returned recently from an extensive trip in northern Italy, where he was engaged in collecting varieties of rice resistant to the disease *brusone*, which he demonstrated to be identical with the blast of rice in America.

DR. FREDERIK VAN EEDEN, of Amsterdam, gave two lectures on March 24 at the University of Wisconsin, on "The Mission of the Poet" and "The Mind in Health and Disease."

PROFESSOR W. E. CASTLE, of Harvard University, delivered a lecture on "Heredity," at the New Hampshire College of Agriculture and Mechanic Arts on March 1.

THE Colorado Chapter of the Society of the Sigma Xi held a banquet on the evening of March 19, after which Professor F. W. Trapnager, of Columbia Chapter, now professor of metallurgy and assaying in the Colorado School of Mines at Golden, read a paper on "Expert Testimony."

PROFESSOR JOHN M. COULTER, of the University of Chicago, addressed the Botanical

Society of Washington on Friday evening, February 12, on "Evolution in Gymnosperms." On March 25 Professor Herbert J. Webber, of Cornell University, read a paper before the society entitled, "Is There a Cumulative Action of Selection?"

THE first course of lectures on the Hitchcock Foundation, which provides for a series of scientific lectures to be delivered annually at the University of California, has just been finished by Professor Julius Stieglitz, of the University of Chicago, on the general subjects of ionization and catalysis. The titles of the lectures were: (1) "The Theories of Solution"; (2) "The Theory of Ionization and Electric Phenomena"; (3), (4) and (5) "Theory of Ionization and Chemical Phenomena," including salt formation, etc.; (6) "Complex Ions"; (7) and (8) "The Electric Theory of Oxidation and Reduction"; (9) and (10) "Catalysis." Professor Stieglitz's lectures were attended by 200 to 300 people, including a number of chemists from the surrounding cities.

THE centenary of the birth of Oliver Wendell Holmes will be celebrated at Harvard University, where he was professor of anatomy and physiology from 1847 to 1882, in Sanders Theater on April 27. President Eliot will preside, and brief addresses will be made by Dr. Edward Waldo Emerson, of Concord, by Col. Thomas Wentworth Higginson, by Dr. David Williams Cheever, and by Rev. Samuel M. Crothers, D.D.

THE committee in charge of a fund for a memorial to the late Dr. Andrew J. McCosh announces that more than \$100,000 has been subscribed. The fund will be devoted to some portion of the new buildings of the Presbyterian Hospital, with the surgical service of which Dr. McCosh was identified.

WE learn from the *Bulletin* of the American Mathematical Society that at the Vienna meeting of the *Astronomische Gesellschaft* it was voted to solicit funds for the erection of a Gauss tower on Hohenhagen, the highest mountain near Göttingen, at the vertex of the Brocken-Göttingen-Hohenhagen triangle with which Gauss experimented con-

cerning non-Euclidean geometry. Ten thousand Marks have already been received. It is desired that this sum may be sufficiently increased to warrant the laying of the corner stone on April 30, 1909, the birthday of Gauss. Contributions may be sent to Professor F. Klein, Göttingen.

WILLIAM HENRY WAHL, author of various contributions to technical science and for twenty-five years secretary of the Franklin Institute, Philadelphia, died on March 23, at the age of sixty years.

DR. GEORGE LORIMER BAKER, of Dorchester, Mass., died on March 19, at East Bridgewater, from tuberculosis which he contracted three years ago while experimenting with its bacilli.

CAPTAIN F. H. HARDY died at Aden on March 8 of sleeping sickness, on the voyage home from Nyasaland, where he had been engaged in scientific research into the causes of tropical diseases.

DR. JAMES HUTCHINSON STIRLING, the veteran Scottish philosopher, died on March 19, in his eighty-eighth year.

THE death is announced of Mr. Thomas Wakley, editor of the *Lancet*, at the age of fifty-eight years. He was the only son of Mr. Thomas Henry Wakley, the late editor of the journal, and a grandson of Thomas Wakley, who founded the *Lancet* in 1823.

DR. EMIL ASCHKINASS, docent for physics at Berlin, died on March 1 at the age of thirty-six years.

PROFESSOR H. MCE. KNOWER, librarian of the Marine Biological Laboratory at Woods Hole, requests us to state that the collection of reprints in the library of the laboratory is very much in need of additions. Publications on the various aspects of biology are in constant demand there. Authors are, therefore, requested to send copies of their publications to this library, where they will be particularly useful.

AMONG numerous charitable bequests in the will of the late Mrs. Emma D. Cummings, of New York, is one of \$25,000 to the pathological laboratory of St. Luke's Hospital.

A COLLECTION of mosses and hepatics has been received by the department of biology of

Princeton University from Dr. Per Duntze and Dr. Hj. Mäller, of Falun, Sweden. The collection consists of about ten thousand specimens, one half of which are Scandinavian.

THE addition to the Hygienic Laboratory of the U. S. Public Health Service, for which the congress some time ago appropriated \$75,000, has just been completed. The addition will be occupied by the divisions of zoology, pharmacology and chemistry and by the library. The original building will be devoted entirely to the division of pathology and bacteriology. Among the more important of the new lines of work recently undertaken in the laboratory is the institution of the treatment of rabies by the Pasteur method and work in connection with the United States Pharmacopœia. The latest publication from the laboratory (Bulletin 47) is from the division of pharmacology and is entitled "Studies on Thyroid. 1. The Relation of Iodine to the Physiological Activity of Thyroid Preparations," by Drs. Reid Hunt and Atherton Seidell.

THE Utah legislature has recently passed a law establishing the Utah Engineering Experiment Station in connection with the State School of Mines, the official name of the engineering college of the University of Utah. The station staff is to be made up of the professors of engineering. And the station is "authorized to carry on experiments and investigations pertaining to any and all questions and problems that admit of laboratory methods of study and the solution of which would tend to benefit the industrial interests of the state, or would be for the public good." The regents of the university will organize the station staff immediately, and the first bulletin under the authority of the station will be published in May. It will give the results of an exhaustive study of the cements on the Utah market.

THE New Zealand correspondent of the *London Times* reports that the Ngauruhoe volcano, which has been quiescent for a year, is now in violent eruption, sending a column of steam, smoke and ashes to a height of 8,000 feet above the crater. The sun for a time

was obscured, and the country is covered with a thin coating of volcanic dust. At Wanganui, some sixty miles distant, a thick haze overhangs the town, and the air is distinctly sulphurous. Violent explosions and rumblings have been heard many miles away.

UNIVERSITY AND EDUCATIONAL NEWS

A BILL now before the Pennsylvania legislature provides for the appropriation of \$950,000 to the University of Pennsylvania, \$475,000 for each of the two years beginning June 1, 1909, and June 1, 1910, the money to be used for: hospital maintenance; new hospital building; the continuation of the new veterinary building; the maintenance of the new veterinary building; maintenance of the general university; increase of the library, and a new building for the department of architecture.

THE Hall of Engineering of Northwestern University, given by Mrs. G. F. Swift and Mr. E. F. Swift, at a cost of \$100,000, was opened on March 24. It will be remembered that Mr. John F. Hayford, of the U. S. Coast and Geodetic Survey, has accepted the directorship of the new school of engineering.

MR. FREDERICK W. VANDERBILT, in addition to his recent gift of a dwelling house for the use of the Sheffield Scientific School of Yale University, has purchased an adjacent house for \$50,000 for the school. With the sale of these two houses the entire square bounded by Wall, College, Grove and Temple streets, with the exception of the building of the New Haven Colony Historical Society and the house on the corner of Grove and Temple streets, in which Noah Webster wrote his dictionary, has passed into the hands of the Sheffield Scientific School.

A HONG-KONG Chinaman residing at Saigon has offered to contribute \$4,000 to the university endowment fund, and he also undertakes to raise \$40,000 among his compatriots in Saigon.

FOR the purpose of founding a Capper Pass chair of chemistry at Britol University Mr. W. Capper Pass, son of the late Mr. Alfred Capper Pass, who was a member of the council of

Bristol University College, has increased his subscription of £4,000 to £10,000.

A CONFERENCE of the deans of the colleges of liberal arts in state universities of the middle west was held at the University of Wisconsin on March 25. Dean Olin Templin, of the college of liberal arts and sciences at the University of Kansas, who is chairman of the meeting, announced a program of four papers to be presented for discussion, as follows: "Method of Grading," by Dean John C. Jones, of the University of Missouri; "Student Organizations," by Dean L. G. Weld, of the University of Iowa; "The Relation of the College to the Other Schools of the University," by Dean Evart B. Greene, of the University of Illinois, and "Advanced Standing," by Dean J. O. Read, University of Michigan.

THE department of engineering of Colorado College will conduct a summer school of surveying at Manitou Park, elevation 7,500 feet, for four weeks beginning June 7. Professor T. B. Sears, of the department of civil engineering at the University of Nebraska, has been chosen director. Several cottages are available for the school and tents are being erected for the accommodation of the students. Manitou Park is on the reserve of the Colorado School of Forestry, twenty miles west of Colorado Springs.

DR. J. H. KASTLE, for the past three years chief of the division of chemistry, of the Hygiene Laboratory, Washington, D. C., has been elected professor of chemistry in the University of Virginia.

M. PERROT, of the Observatory at Meudon, has been appointed professor of physics in the Paris Polytechnic School to succeed M. Becquerel.

M. CAULLERY has been appointed professor of zoology at Paris to succeed the late M. Giard.

DISCUSSION AND CORRESPONDENCE

AMERICAN CHEMICAL HISTORY AND BIOGRAPHY

TO THE EDITOR OF SCIENCE: Having been appointed historian of the American Chemical Society and having arranged for the care of its documents by the Smithsonian Institution, I

earnestly request chemists throughout the country to send to me for safe-keeping in the Smithsonian Institution such historical and biographical documents of American chemical history and biography as they may be willing to part with. They will be kept together, catalogued and be easily accessible to chemists, students and other proper persons. Just at present papers by the late Dr. Wolcott Gibbs are particularly desired. Questions of precedence and patent questions may be decided by such a concentration of documents in a single accessible place. Please address them to The Smithsonian Institution, Washington, D. C., care of Dr. Alfred Tuckerman.

ALFRED TUCKERMAN

NOTES ON FISHES AT CORSON'S INLET, NEW JERSEY

ON March 1, 1909, in company with my friend, Dr. R. J. Phillips, the salt-ponds on the meadows at this locality were examined for small fishes. We were rewarded by securing three fine examples of the rare *Fundulus lucia*, a small cyprinodont described from the Great Egg Harbor region by Baird in 1854. As this is the first definite instance of its occurrence in New Jersey waters since that time I have thought it well worthy of record. Dr. T. H. Bean visited the region of the type locality in 1887 and after a careful search failed to locate the fish. The rediscovery of the species was made by Dr. H. M. Smith in the lower Potomac River in 1890, and was based on two small specimens. Baird's types were not then believed to be extant. Our specimens were found associated with numerous small amphipod crustaceae, *Orangon vulgaris*, numbers of *Palæmonetes vulgaris*, small transparent *Anguilla chrisypa*, numerous *F. heteroclitus macrolepidotus* of all ages, many *Lucania parva*, great numbers of *Cyprinodon variegatus* and a single example of *Menidia beryllina cerea*. Dr. Phillips picked up a fine example of *Gobiosoma boscii* on the beach, and on February 15 he secured in a rain-pool on the barrier beach a number of specimens of *Gasterosteus aculeatus* and one of *Pygosteus pungitius*, the latter being the most southern record on the New Jersey coast

we know of. Quite a number of *Pseudopleuronectes americanus* were reported by the fishermen recently, and *Ammodytes americanus* was several times noted during the past winter.

SCIENTIFIC BOOKS

The Mechanical Engineering of Steam Power Plants. By DR. F. R. HUTTON, Professor Emeritus, Mechanical Engineering, Columbia University. Third edition. John Wiley & Son.

The first edition of this work appeared in 1897 and it has become a standard work of reference in its class. The third revised edition contains some changes in arrangement of topics and material which brings the work up to date. In the last edition the steam turbine is fully described and its advantages, as compared with the piston engine, thoroughly discussed.

There are various technical works which relate to specific machines required for the generation of steam power, but only a few which are devoted to the installation and arrangement of these various machines so as to produce the most economic result, which is the branch of engineering to be considered in the design and installation of the machinery for a complete power plant. The modern power plant involves such a large variety of machinery that its construction constitutes a complicated problem, and it is necessary for the designer to be thoroughly acquainted with the various types of machines and the different varieties of each in order to make an aggregation, of which all the parts will co-act and perform their functions so as to produce the highest economic results. It is obvious that a steam power plant must contain "steam-making" machinery, "steam-using" machinery and the various elements required for transmitting the steam from where it is generated to where it is usefully applied. A knowledge of the industries of this country reveals numerous manufacturers engaged in the production of different vari-

eties of these elements, each of which has special merits for certain conditions and is utterly unsuited for others. In addition to the principal elements above enumerated each power plant must contain various accessory machines, as for instance, pumping installations for feed water, condensers, etc., and under certain conditions it is economical and desirable to supply various appliances for regenerating or saving heat which would otherwise be wasted, such as feed water heaters, economizers and coverings for pipes. When it is further considered that there are several special manufacturers for each of the minor kind of machines, one can readily understand that the field, which is open to Dr. Hutton, is a very extensive one.

In Dr. Hutton's treatment of the problem a full description has been given of the principal forms of boilers, various boiler accessories, furnaces, chimneys and setting, also systems of piping and the accessories for the removal of water and oil.

The principal portion of the work is devoted to "steam-using" machinery and its accessories. In this part full descriptions are given of the principal forms of piston engine and steam turbines, and also a discussion of the theory of action of these machines. The pumping machinery, condensers, construction of foundations, are also thoroughly considered.

The book contains 825 pages and nearly 700 illustrations.

The reader of the work is quite likely to regret that so much space is given to the description and theory of various elements of the power plant, all of which matter can be readily found in special treatises which find a place in practically every mechanical engineer's library, and on the other hand, that so little space is given to the proportioning and coordination of the various elements with each other and to the practical commercial problems which must be worked out in connection with the erection of every plant.

On the whole the book will prove useful to any one engaged in the study of the problem of supplying machinery for the production of power.

Professor Hutton states in his preface that the object of the book is largely the study of "function and purpose of power plant apparatus," and from that standpoint the book is certainly a successful treatise.

What Professor Hutton states respecting the future displacement of the piston steam engine by the steam turbine is doubtless true and is, I believe, of general interest. He states in effect in his preface that the steam turbine has a special field which is limited in a large measure to large units and to the use of electrical transmission and that the piston engine will always be superior for smaller units, and where a large starting torque is necessary, and he also could have added where a vacuum is not possible.

The question has often been raised by the public and investors as to the possible displacement of steam machinery by the internal combustion or gas engine. Dr. Hutton shows that such displacement is not probable, for although the thermal efficiency is higher in the internal combustion engine than in the steam engine, the cost of fuel per unit is generally greater and the repairs and maintenance are much higher. It is not probable that the internal combustion engine will ever replace the steam engine where large power units are necessary. The principal field of the internal combustion engine is that where small powers are required and where the prices of fuel per unit, labor or repairs would be offset by the extra amount of fuel or complications of a steam plant.

R. C. CARPENTER

CORNELL UNIVERSITY

An Introduction to Electricity. By BRUNO KOLBE. Being a translation of the second German edition (1904-5) by JOSEPH SKELTON. Cloth, 8vo, pp. viii + 430. Philadelphia, J. B. Lippincott Co.; London, Kegan Paul, Trench Trübner & Co. 1908.

This book is written in the form of lectures to a class of beginners with little preparation in either mathematics or mechanics. It begins with the electrification of amber, the oldest experiment known to electrical science,

and ends with a brief description of radio-active phenomena. This, together with interesting historical and practical matter, is contained in an appendix. The main body of the work is almost entirely taken up with the older and more fundamental portions of the pure science and some of its most important applications. The lectures are illustrated with abundant, but not too numerous, experiments, most of which are both excellent in themselves and described in a clear and interesting way. Many would do well to follow the author in his extensive use of the gold leaf, or aluminium leaf, electroscope provided with a scale; in discarding the torsion balance for a more modern instrument; in the use of amber as an insulator; and in the use of a straight wire sliding on metal rods across a magnetic field to show the motional electromotive force—all of which are fortunately becoming more and more common. The general plan of the work is good. Its style, though ordinarily clear, is marred by many obscurities and other infelicities of expression, many of them due to clumsiness of translation. Perhaps the most obscure paragraph in the book is that in which the action of the Holtz machine is explained. The author is particularly unhappy in the character and extent of his nomenclature for potential and fall of potential, some of his names for these quantities being electroscopic state, degree of electroscopic state, degree of electrification (even when the point whose potential is referred to is not on an electrified body), degree of electricity, intensity of electric field, measure of the degree of electrification in units of work, fall of electricity, fall of potential, polar difference, fall of the stream. This, however, is much the worst case of the kind that occurs. We read that a hollow metal ball can absorb electricity, that electricity is a puzzling force, that electric forces act on each other, of the conversion of electricity into work, and *vice versa*; and we find many other expressions entirely out of place in a work aiming to be scientific, and very objectionable anywhere else. The author wisely devotes but slight attention to the consideration of hypotheses;

and fortunately, as it seems to the reviewer, for his treatment of several at least of those taken up appears far from sound. It is a more serious matter that the book is in error as to many matters of fact and theory too well established to question. Thus, for example, a very curious and erroneous explanation is given of the action of flames in discharging electrified bodies. Electric absorption is explained by the statement that the spark discharge takes place so quickly that all the electricity can not follow and a residuum remains. The influence machine is classed with the dynamo as a highly efficient source of electricity. The great advantage of the D'Arsonval galvanometer, called the solenoid galvanometer, is said to be that it does not have to be set up with its coil in the magnetic meridian. Self induction is explained as a particular case of mutual induction. All dynamos are said to give the best results when the resistance in the service conductor is equal to that in the windings of the machine, and we are told that stronger hard-soldered thermopiles are specially suitable for the charging of accumulators. One of the first errors made in the book is in the discussion of an experiment on capacity, which the author mistakes for an experiment on potential—a quantity which has led astray so many writers of elementary books. In this connection we read, as we have read in other books, that a positive body gives up electricity to the earth and that a negative body receives electricity from the earth; but we are not told what the earth itself does when it is either positively charged or negatively charged. No correct definition of the electromotive force of a generator is given, and no satisfactory derivation of Ohm's law for a closed circuit. Under the circumstances we are not surprised to read that Ohm's law does not hold for alternating currents. These matters are so fundamental, and so easy to treat properly, that the remissness of text-book writers is hard to understand. The statements in the appendix with reference to what should be called the electric intensity and the electric tension at the surface of a charged conductor are anything but satisfactory. The

dyne is wrongly defined, velocity is wrongly expressed. In a number of cases equalities and proportionalities are used indiscriminately. In fact, the book is logically weak, as would be expected from the author's statement that "inquiry into the rules of dynamics would carry us too far afield." Much dynamics and much mathematics are wholly unnecessary for the purposes of this work, yet its merits would be greatly increased by the more exact use of the little necessary. The book is provided with a good table of contents and a good index. It is well bound and excellently printed. The misprints noted by the reviewer are exceedingly few.

S. J. BARNETT

Arbeiten aus dem Gebiet der Experimentellen Physiologie. Herausgegeben von Dr. HANS FRIEDENTHAL in Nicolasssee bei Berlin. Mit 4 Tafeln und 14 Figuren im Text. Jena, Gustav Fischer. Pp. 493. 1908. Price, 8 Marks.

This collection of papers by Dr. Friedenthal and his collaborators has been prepared in order to bring together a number of contributions scattered throughout various scientific journals, some of which are not easily accessible, and to make them readily available to physiological readers. They have been arranged by the editor, with relation to their content, into the following groups: biological relationships among animals and plants; papers on physiological operative technic, including studies on absorption, the innervation of the heart, and the sympathetic system; studies on physical and physico-chemical topics; papers on the H-ion concentration and the reaction of living substance; and additional contributions of diverse character.

It is impossible here to refer individually to the 55 papers reprinted. Many of them are already quite familiar to biological and physiological workers. This applies, for example, to studies such as those dealing with the fate of foreign sera introduced into the circulation of animals, and with the nature of the forces coming into play during the act of absorption. Friedenthal defends the view that solubility in water is *per se* insufficient to determine the

possibility of absorption of substances by cells. We are asked to distinguish between solubility in protoplasm and solubility in water; herein the now well-recognized importance of the cell lipoids for the processes under discussion is duly emphasized. The author has furthermore especially insisted upon the absence of special "vital" forces in absorption.

Friedenthal's earlier observations on the biological relationships of animals and the position of man in the zoological scheme were perhaps not as widely known at the period of their publication as they deserved to be; the so-called "immunity" reactions which were shown in common for man and the anthropoid apes have since been more extensively observed.

Some of the observations on the occurrence and nature of enzymes have more recently lost the significance attributed to them when they were first published. Thus Friedenthal's announcement of the existence of an amylolytic enzyme in the gastric juice of dogs is probably referable to the regurgitation of intestinal contents (including pancreatic secretion) into the stomach—a phenomenon shown by Boldireff to occur with frequency in these animals.

The most significant of all the reprinted papers are, perhaps, those dealing with the reactions of the blood and protoplasm. Friedenthal was among those first to point out the non-existence of an alkaline reaction in the blood in reference to indicators sensitive to carbonic acid; and he showed the importance of the alkali bicarbonate of the serum as a regulatory factor in preventing marked variations from neutrality. These investigations were followed by the publication of a comparatively simple method for the estimation of the reaction of physiological fluids by the use of a series of indicators. The method, which has already found application in the study of physiological problems, is likely to be a help in future research, especially in the study of such questions as acidosis.

Lectures on the Elementary Psychology of Feeling and Attention. By EDWARD BRADFORD TITCHENER. Pp. x + 404. New York, The Macmillan Co. 1908.

This volume contains eight lectures given while the author was non-resident lecturer in psychology at Columbia University in 1908. As the title implies, they give a résumé and critical discussion of the recent work and current theories of psychology on the two topics mentioned.

The first chapter contains a discussion of sensation and its attributes. The attributes are broadened beyond current usage to seven. They are divided into two groups. The intensive, in which are grouped the familiar intensity, duration and extent together with clearness; the qualitative attributes, that for sight would include hue, tint and chroma. Differences in kind of sensation depend upon distinguishable differences in the qualitative attributes; differences in degree upon differences in the quantitative attributes.

Chapter II. is devoted to a consideration of the criteria that distinguish affection from sensation. It is often asserted that feelings and sensations are different in that we become habituated to feelings not to sensations, that feelings are centrally relatively more intense, that feelings are subjective, sensations objective; the one is non-localizable, the other localizable; that feelings exhibit antagonism in quality and are unclear, while sensation qualities are not necessarily opposed and are or may be clear. The first two of these criteria are rejected absolutely, the next two are held to be doubtful, while the last two alone are retained.

Chapter III. discusses Stumpf's doctrine of feeling as a special kind of sensation, sense feeling. The doctrine is rejected as out of harmony with introspective results and supported by rather uncertain psycho-physical evidence. The fourth chapter is devoted to Wundt's tridimensional classification of the feelings with the same negative result.

The fifth chapter begins the discussion of attention with a discussion of the nature and

conditions of clearness. Clearness and attention are identified. The conditions of clearness are found ultimately in the nervous disposition, the predisposition of the central nervous system and sense organs. The sixth and seventh lectures are devoted to the laws of attention. The first asserts that clearness is an independent attribute of sensation; the second that there are always two levels of clearness to be distinguished, although the rigidity of the distinction is softened by the statement that there are minor differences of clearness within each level. The third law is that the peripheral and central adaptation requires time and that as a result (4) there are temporal displacements since these accommodations bring earliest to consciousness the stimulus to which the organism is adapted. The object of attention is always a unitary field within which several part contents may be distinguished. The fluctuations of attention are referred to the periphery. There is finally the hope expressed that it may be possible some day to determine the law of the degree of clearness, but the most that can be done at present is to discuss the various methods that have been suggested for the measurement of attention.

In the final chapter affections would be identified with the unclear elements of consciousness; their sense organs have not yet become fully differentiated. Attention and feeling are positively related. We can attend without feeling, but can not feel without attending. Attention increases the effectiveness of feelings as it does of sensations. Attention is characterized in addition to clearness by its relation to will in the Wundtian sense. Passive and active and secondary passive are retained as real distinctions and supported on genetic grounds. The final theory of attention is in close agreement with Wundt.

These are the outlines of the book, but a summary can give no idea of the painstaking care with which the sources have been gone through, nor of the scrupulous endeavor to give every man and every theory its due. There is a refreshing absence of anything that even approaches dogma, and the greatest

possible readiness to leave a problem open rather than to venture a solution that shall be at all one-sided. In fact, if there is any criticism to be passed it is that anxiety to be absolutely fair to the views of others sometimes prevents the author from stating his own with the positiveness that makes for definiteness. If one wants a statement of recent theories and the established facts in feeling or attention the volume is to be recommended as the best available. It gives not merely a clear, full and sympathetic statement of the theories themselves, but a measured and undogmatic criticism, and the resulting theory of the author.

W. B. PILLSBURY

UNIVERSITY OF MICHIGAN

Camps and Cruises of an Ornithologist. By FRANK M. CHAPMAN. With 250 photographs from nature by the author. Pp. xvi + 432. New York, D. Appleton & Co. \$3.00.

As its title indicates, this book is a series of narratives. But, though popular in style, it is not lacking in seriousness, for it contains many fresh or new observations on the habits of birds which will be of permanent value to ornithologists. It is based largely on the author's field work in gathering material for the now rather well-known "habitat groups" of birds exhibited by the American Museum of Natural History. Therefore, it may appropriately be called a by-product of museum work, and, as such, though published privately, it admirably illustrates the way in which a modern natural history museum may carry its broadening influence beyond its exhibition halls.

The eight sections into which the book is divided contain related chapters, each devoted to a certain species or a single expedition. Some of these have been published previously in periodicals and others will be recognized in certain quarters as having been the subjects of public lectures, but some are entirely new and all are pleasing in style and either replete with real information or most suggestive of possibilities in specialized bird study.

Travels about Home, the first section, includes a few little intimacies with blue jays,

meadowlarks and nighthawks and indicates the opportunities for bird study that lie close at hand, even to the busy New Yorker. The next, *Bird Life of Two Atlantic Coast Islands* (Cobb's Island and Gardiner's Island), deals with some interesting species of water birds likewise found at home but a short distance from our largest cities. *Florida Bird Life*, following, is notable for its almost exhaustive study of the brown pelican and its revelations of the secrets of the great rookeries of herons and egrets, including the now rare experience of meeting the roseate spoon-bill in the breeding season. *Bahama Bird Life* includes observations on terns, boobies and man o'war birds, but easily takes first rank for its superbly illustrated and fascinating story of experiences in the wonderland of flamingoes. The *Story of Three Western Bird Groups* briefly relates incidents of visits with the prairie chicken in Nebraska, the golden eagle in Wyoming and various small desert birds in Arizona. This is followed by *Bird Studies in California*, which is introduced somewhat modestly, perhaps in deference to the splendid work being done by Pacific coast ornithologists; but, in view of the limited time spent in the field, most creditable results are shown, especially in the chapters on the water birds of the San Joaquin Valley and of Lower Klamath Lake. *Bird Life in Western Canada*, like most of the book, is devoted to water birds, with the exception of a chapter on the white-tailed ptarmigan and other birds of the higher parts of the Selkirk Mountains. The concluding section consists of the single chapter, *Impressions of English Bird Life*.

The half-tone illustrations, 250 in number, are mostly of that excellent character regularly attained by our best bird photographers. The few that are not technical gems of photographic skill are quite justified by their ornithological interest, while some certainly deserve rank among the most interesting and successful bird photographs ever taken. Typographical errors and a few other slight evidences of haste while the book was in press are rather too frequent to be over-

looked. It is hoped that these will be corrected in later editions.

WILFRED H. OSGOOD

BOTANICAL NOTES

GANONG'S PLANT PHYSIOLOGY

SEVERAL years ago Professor Ganong wrote a very useful little book on plant physiology, which is now expanded into an octavo volume of 265 pages under the title of "A Laboratory Course in Plant Physiology," brought out by Holt in a very handy form for laboratory use (\$1.75). The author tells us that the book has a threefold purpose, namely, (1) "to lead students through a good laboratory course in plant physiology"; (2) "to provide a handbook of information upon all phases of plant physiology having any educational interest"; (3) to serve "as a guide to self-education by ambitious teachers or students, who, unable to obtain regular instruction, yet wish to advance themselves in this attractive and important subject."

In pursuance of these objects the author devotes about fifty pages to helpful discussions on the place of plant physiology in botanical education, methods of teaching and study, greenhouse and laboratory plans, apparatus and material. This is followed by the book proper, in which the sequence of subjects is (1) the structure and properties of the protoplasm of plants; (2) the physiological processes of plants, the latter including (a) the processes of nutrition (photosynthesis, chemosynthesis, synthesis of proteids, conversion, respiration, absorption, transport, elimination); (b) the processes of increase (growth, reproduction); (c) the processes of adjustment (irritable response, adaptation). A closing chapter of a dozen or so pages is devoted to methods of manipulation, and to convenient tables and lists.

Looking over the pages of the book, the reader is impressed with the practicability of the suggestions made by the author. They impress one as being based upon much experience, and this is actually the case, for the book is a growth from Professor Ganong's long and successful experience with students

in his own classes in plant physiology. The illustrations (68 in number) and full-page plates (4) are especially helpful, and yet not an illustration or plate has been given merely to make the book appear more attractive; every one is needed; every one helps to make some part of the subject more clearly understood. Altogether this is one of the most satisfactory botanical text-books in any department of the science that has come to our notice.

ECONOMIC BOTANY

THE Report of the Chief of the Bureau of Plant Industry of the United States Department of Agriculture for 1908 is an encouraging paper, showing as it does the steady enlargement of the scientific study of plant problems. A full enumeration of all of the work carried forward is impossible here, but the following general outline may give some notion of its extent: Field and laboratory work in pathology and bacteriology; plant life-history investigations; investigations of drug and other special crops, and of poisonous plants; crop technology, cotton standardization and fiber investigations; grain standardization; seed laboratory; physical laboratory; investigations and experiments in the semi-arid west and southwest; demonstrations and experiments with field crops; Arlington experimental farm and truck-crop investigations; investigations in pomology; greenhouses, gardens and grounds; farm management investigations; farmers' cooperative demonstration work; work connected with the purchase and distribution of seeds; special testing gardens in the field. Under each of these heads are details of many experiments and studies of great botanical interest, and of still greater interest to farmers, gardeners and other growers of plants. Indeed, one can scarcely open a page of this pamphlet of 135 pages without finding an interesting and suggestive paragraph. The people of the country have reason to be proud of this bureau of our National Department of Agriculture.

Another paper which appeals to the economic botanist is one from the New York Agricultural Experiment Station, entitled

"Troubles of Alfalfa in New York" (Bull. 305), in which are taken up such things as: uncongenial soil conditions; winter injury; dodder; weeds; fungus diseases; root-knot; diseases of unknown cause, etc. The whole paper is full of interesting facts for the grower of alfalfa, and most of it should interest the general botanist. The portion dealing with dodder (*Cuscuta*) is especially interesting. A valuable bibliography including 115 titles closes the bulletin.

In a recent number of the Kew Bulletin of Miscellaneous Information Mr. Fred Turner's paper on "The Economic Value of the Australian Pasture Herbs" is interesting to American botanists as showing the great differences between the two countries. His list includes a *Trigonella*, *Erodium*, *Geranium*, *Boerhaavia*, *Blennodia lepidium*, *Marsilia*, *Daucus*, *Psoralea*, *Swainsona*, *Plantago*, *Calandrinia*, *Portulaca* and *Tetragonia*. Of the *Marsilia* (*M. drummondii*) he says:

This dwarf, clover-like plant, occurs in the interior of all the Australian states, generally on the margins of swamps or where water collects in shallow pools after rain. When the water subsides the young plants grow rapidly in the mud, and eventually cover the ground with dense vegetation, reminding one of cultivated clover. All kinds of stock are extremely fond of this plant, which is regarded as nutritious food.

PAPERS ON FUNGI

An important paper on the "Geoglossaceae of North America," by Mr. E. J. Durand, appeared recently in "Annales Mycologici" as one of the contributions from the department of botany of Cornell University. These plants are discomycetous fungi of somewhat doubtful affinities, Shroeter associating them with *Rhiziniaceae* on the one hand, and *Helvellaceae* on the other in the order *Helvellales*, while Boudier places them near *Heliotiaceae* and *Mollisiaceae* in *Pezizales*. With the latter view Mr. Durand agrees. In his paper, after an interesting introduction of nine or ten pages, the author makes a synopsis of the eleven genera considered, and then follows with full generic and specific descriptions, with exact citations of all the material

examined in every instance. This portion of the paper, with index and explanations of the plates, fills eighty pages, and these are followed by eighteen plates, nearly one half being made from photographs. Forty-two species are recognized, and of these nine are here described for the first time. The paper should do much to stimulate the search for the plants of this group of fungi.

A recent number of the *Bulletin* of the College of Agriculture, of the Tokyo Imperial University of Japan, contains two important papers on fungi by the Japanese botanist, S. Kusano. One of these is entitled the "Biology of *Chrysanthemum Rust*," and discusses "black rust" (*Puccinia chrysanthemi*), "white rust" (*P. horiana*) and "brown rust" (*Uredo autumnalis*). The exact relationship of the latter has not yet been determined. The opinion is expressed that the rusts occurring on cultivated species of *Chrysanthemum* in Japan originated upon the wild *Chrysanthemum* of that country (*C. decaisneanum*).

The second paper by Kusano, under the title of "Notes on Japanese Fungi," is in continuation of a series of articles on this subject, the present one being devoted to species of *Puccinia* known to occur on the leaves of bamboo plants. Five species are enumerated, viz.: *P. phyllostachydis* (on *Phyllostachys bambusoides*); *P. longicornis* (on *Sasa paniculata* and *Arundinaria japonica*); *P. kusanoi* and its variety *azuma* (on *Arundinaria simoni*, *A. variabilis*, *A. naharia* and *Sasa* spp.); *P. sasae* (on *Sasa borealis*). From observations on these rusts the author concludes that "it is highly probable that the uredosori originate from the sporidia," that is, without the intervention of the accidial stage.

CHARLES E. BESSEY

THE UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

THE OTTER IN EASTERN MASSACHUSETTS

IN a recent number of SCIENCE Mr. C. E. Gordon reports that otters have been repeat-

¹ Vol. XXVIII., No. 726, November 27, 1908, pp. 772-775.

edly taken or seen within the past three years along the Connecticut River valley in central Massachusetts. He thinks they have been increasing there of late and his evidence, when compared with that of earlier writers, seems to show that they are at least as numerous represented now as they were fifty or sixty years ago. In his opinion it is "possible to postulate the persistence of these animals in this state as a logical consequence of their shy habits and tendencies to roam about" although their "abundance" "in the Connecticut River valley has suggested" to his mind "that they have come along this waterway from the north outside the limits of the state to the smaller tributaries of the river in the lowland of the valley," whence "they may have traveled eastward through the valleys of the Ware, the Assabet, and the Blackstone to the seaboard." There is, too, he believes, a "possibility of their having come along another waterway from the north—the Merrimac, along the tributaries of which—the Concord and the Nashua—they might have easily made their way southward." He says further, the "comparative scarcity" of the otter "in the eastern part of the state is noteworthy." Of its recent occurrence there he is able, apparently, to give but one instance—on the authority of Dr. Glover M. Allen, who "found unmistakable tracks of the otter near Dedham, Norfolk County, two winters ago."

That otters may occasionally reach central Massachusetts from northern New England by way of the Connecticut River is not improbable, for they are restless, wide-roving creatures, accustomed to making long journeys through convenient waterways and also to traveling overland from pond to pond and stream to stream, sometimes over high mountain ridges. I suspect, however, that at the present time they are more likely to move up than down the Connecticut, for Mr. Gordon's testimony indicates that they are now more plentifully represented along the Massachusetts reaches of that river than in the wilder regions near its source—of which I know something from personal experience.

I have been familiar with Concord River and with the lower reaches of the Assabet, for upwards of forty years. If, during this period, otters have frequented, or even casually visited either of these streams, the fact remains unknown to me. But they have been found to my knowledge along the Sudbury River, not far above where it unites with the Assabet to form the Concord, and most frequently, I believe, in or near what is known as Fairhaven Bay, a shallow expansion of the Sudbury, lying partly in Concord and partly in Lincoln. Here my friends, Mr. Charles M. Carter and Mr. George C. Deane, had a good view of one, in broad daylight, early in the month of June, 1876. It swam across the bay from shore to shore, moving through the water swiftly and carrying its head well above the surface after the manner of its kind. During the next ten or twelve years I heard repeatedly of otters that had been seen or tracked by local hunters and fishermen of my acquaintance, either along the river or its small tributary streams, and invariably within a mile or two of the bay. One man in whom I had full confidence reported finding fresh otter "slides" in the deep, boggy hollow which the Fitchburg Railroad crosses just to the eastward of Walden Pond and which forms the source of a cold trout brook that flows into Fairhaven Bay. Another account, for the truth of which I can not vouch but which, as I remember, was very generally credited at the time, related to an otter said to have been killed in midwinter in the public road near the bridge that spans the river just above the bay, by a farmer who lived at Nine Acre Corner, an outlying settlement of Concord. As the story ran, this man was wending his way homeward through deep snow, late one stormy night, when he was startled by the sudden appearance of the otter directly in front of him and only a few yards away. On seeing him it left the road and plunged into a snow drift, which so impeded its further progress that he overtook it without much difficulty and despatched it with a stick.

A man living in Lincoln, about a mile and

a half to the eastward of Fairhaven Bay, assured me, in the summer of 1889, that otters were then frequenting a meadow near his house. He thought there were at least two or three of them and he feared they were preying on some trout that he had put in a series of connecting ditches filled with clear, cold water. I heard the following year that despite his repeated attempts to shoot and trap them, they finally departed unharmed, after haunting the meadow for several months and eating the last of his trout. As far as I am aware there is no later instance known of the occurrence of the otter in the region about Fairhaven Bay, but if it be still found in Charles River it is likely to reappear at any time in the Sudbury, for these streams approach one another closely in several places.

For the Charles I have a manuscript record pertaining to a time less recent than that when Dr. Allen's observation was made, yet not so very long ago. It is on the authority of Mr. Shelley W. Denton, who, in February, 1894, obtained definite evidence that an otter had been killed, about the fifth of that month, in South Natick. It appeared early one cold morning on the ice at an air hole and fell a victim to a well-aimed shot fired by a man named Frank Carroll from the window of a stable that stood on the edge of the river not far from the village.

In the towns of Readville and Canton, only ten or a dozen miles to the southward of Boston, otters were not uncommon less than twenty years ago. They were seen occasionally in the Neponset River and my friend Mr. Roland Hayward often found their tracks on the banks of certain of its tributary brooks which he was accustomed to fish for trout. Most of his fellow fishermen, the otters, seem to have eluded the local hunters and trappers, but one was shot in Ponkopog Pond on March 30, 1893, by the Messrs. Charles W. and J. H. Bowles. It came swimming in from the middle of the pond directly towards the brush stand on the shore, where they were lying in wait for ducks. On reaching their little flock of *wooden* decoys it seized one of these in its teeth, when Mr. J. H. Bowles fired, killing it almost instantly. He or his brother

skinned and mounted it. The specimen now forms one of the most attractive wall ornaments of my private museum, for they were kind enough to give it to me when, a few years later, they went to the Pacific coast. It is an exceptionally large and handsome animal, in dark, richly colored pelage. Mr. F. B. McKechnie, who now lives in the house at Ponkopog formerly occupied by the Bowles family, tells me that he has seen no other signs of late in the Neponsett River valley although he has heard that two otters were trapped in the autumn of 1907 in the Neponsett meadows, by Mr. Rogers. He further informs me that Mr. Arthur Smith saw the track of an otter near Blue Hill about three years ago.

If, as seems not improbable, the recent presence of otters in some numbers in the lower portions of the Neponsett River valley has been due—at least in part—to immigration from regions somewhat more remote, the influx is likely to have come, not from the north, but from the south. For it is neither known to me nor probable that these animals have occurred plentifully of late anywhere immediately to the northward, whereas at no great distance to the southward, throughout most of the wooded parts of Cape Cod, they are—or have been recently—much more numerous represented than I have ever found them to be elsewhere in New England, even about the lakes and rivers of northern Maine and New Hampshire. Nor is this surprising, in view of the fact that very much of the Cape remains unsettled and, indeed, essentially a primitive wilderness, which, although somewhat over supplied with keen and successful hunters of deer, foxes, game birds and waterfowl, has almost wholly lacked expert native trappers because of the general scarcity or absence, for half a century or more, of furbearing animals of any considerable value. It has, too, among other attractions, innumerable ponds and streams, such as the otter loves to frequent; for most of these are filled to the brim at every season with clear sparkling water and bordered by dense woods and thickets, or fringed by reeds or by cat-tail flags, while nearly all abound with fish of

one or another kind. They are, moreover, not only numerous and wide-spread, but also frequently joined to one another by rivulets or by springy runs and bushy swamps; so that they form, in effect, extended and intricate systems of more or less perfectly connected waterways, through which semi-aquatic creatures like the otter can roam at will over wide areas without often having to cross dry land. Such conditions suit the otter perfectly. Favored by them and also, for a time, by almost complete immunity from molestation, he thrived and multiplied on the cape until he had repopulated most of his ancestral haunts. That the period during which he re-occupied these in any number does not date far back nor quite down to the present time, I will now attempt to show.

My first visits to Cape Cod were made in 1866 and 1867. Between 1871 and 1878 I went there almost every year, sometimes in spring or summer to collect the smaller birds of the region or their eggs, often in late autumn for the quail and duck shooting. During these trips I became familiar with many of the ponds and streams in Plymouth and Barnstable counties. If they harbored otters in any numbers at that time I failed to learn of the fact, either through personal observation or from local hunters whom I employed as assistants or guides. All these men agreed, if I am not mistaken in my recollection, that the otter was then, and had been for many years previously, so very rare throughout the cape region that even its tracks were seldom seen. About 1890 (it may have been a year or two earlier or later) I began to hear rather frequently of otters that had been seen or tracked on Cape Cod. In the course of the next decade they increased in numbers and extended their distribution until they had become of common occurrence almost everywhere from Wareham and Plymouth to Brewster and South Yarmouth. No doubt they ranged still farther eastward along the cape, if not also northward to Canton and Readville, as I have already suggested. They seem to have reached their maximum abundance about the beginning of the present century. Up to this time they

were not much molested, for they are exceedingly wary creatures and few of the local hunters knew how to capture them: but within the past five or six years, as I am informed by Mr. Outram Bangs, the Marshpee Indians have trapped them systematically, not only in the Indian Reservation near Cotuit, but elsewhere over the cape, and with such skill and success that they have been everywhere very considerably reduced in numbers. When they were still plentiful I saw their signs in many places about the sandy or muddy margins of ponds, brooks and swamps in Plymouth and Barnstable counties, usually in places remote from civilization, but sometimes—as at South Yarmouth—within a mile of village centers and even nearer outlying farm-houses, while I have occasionally tracked them from pond to pond over high ridges traversed by public roads. Mr. Bangs has had still more frequent and interesting experiences of a similar kind, for his summer home at Wareham lies within easy reach of many an otter-haunted pond and stream. When I was visiting him there in 1900 he took me one day (June 13) to a wide, swift-flowing brook into which an otter, disturbed by our approach, had evidently plunged only a few moments before. The eddying water was still roily where he had entered it and on the shore we found his footprints and a dead alewife that he had been eating. It was perfectly fresh and, indeed, still bleeding at the point where its head had been bitten off. No doubt this was the same otter that Mr. Bangs had seen near the same place only a week or two before and it may have been also the one that he shot there some three years later (on March 31, 1903), whose mounted skin is now on exhibition in the Museum of Comparative Zoology.

The evidence above presented is undeniably too fragmentary and inconclusive to positively discredit Mr. Gordon's suggestion that eastern Massachusetts may have been restocked, within recent times, by otters that have come directly from Maine and New Hampshire or indirectly thence by way of the Connecticut River and such eastward-flowing streams as the Assabet. Indeed, I am by no means dis-

posed to deny that this may have happened. But I consider it much more probable—as does Mr. Gordon apparently—that most, if not all, of our otters (at least those found in eastern Massachusetts) are descended from primitive native stock. For it is evident that the species has never been completely extirpated in Massachusetts, even in the neighborhood of such large cities as Boston and Springfield, while any assumption that there have been immigrations from farther north is unsupported by known evidence and also unsatisfactory because of the fact (to which I could bear strong testimony if it were necessary) that in most parts of northern New England otters are, and have been for twenty years or more, far from common. Hence it is difficult to believe that many of them have come to us from that direction, although a very few may stray southward, at infrequent intervals, along the Connecticut and Merrimac rivers. However this may be, I am decidedly of the opinion that if, within recent times, there has been anything in the nature of an overflow of otters from localities which they have somewhat over-populated, its source is most likely to have been Cape Cod. For there, as I have said, the otter has been more numerously represented, over wide areas, during the past quarter of a century, than anywhere else in New England.

CAMBRIDGE, MASS.

SOCIETIES AND ACADEMIES

THE GEOLOGICAL SOCIETY OF WASHINGTON

At the 212th meeting of the society, held on Wednesday, January 13, Mr. G. K. Gilbert presented the following paper: "Earthquake Forecasts," a paper read before the Association of American Geographers at Baltimore, on Friday, January 1. This paper was published in *SCIENCE* and hence no abstract is furnished herewith.

At the 213th meeting of the society, held on Wednesday, January 27, the following papers were presented:

Regular Program

Some Observations on Rocky Mountain Faults:
CHESTER W. WASHBURN.

The faults observed may be referred to three genetic types.

Type I. Normal dip faults crossing the axes of anticlines.—The examples considered displace strata just above the Colorado shale, and do not penetrate the latter over 300 feet. None reach the Carboniferous. The maximum vertical displacement, 50 to 300 feet, is on the anticlinal axes and decreases down the limbs until the faults become small monoclinical flexures and finally disappear. The motion along each fault plane had two essential components: (1) vertical, either (a) upward movement of the foot-wall, or (b) downward movement of the hanging wall; and (2) horizontal, either (a) inward movement of the foot-wall toward the anticlinal axis, or (b) outward movement of the hanging wall away from the axis. Field observations show that these movements have been combined in one of two ways. A: (1a) with (2a); or B: (1b) with (2b). Combination A would be produced during folding by compression resulting in axial thickening of the underlying shale and upward creep on the limbs, the movement being greater on the up-thrown or foot-wall side of each fault. Combination B would be produced by creep down the limbs of anticlines and axial thinning of the Colorado shale, the movement being greater on the down-thrown side. This might be caused during the folding, by the tension of stretching over the underlying Paleozoic limestones, or subsequently by gravitative creep down the limbs, under the pressure of about 3,000 feet of overlying rock. Combination A is the most probable. The breaks were probably initiated as lines of scission or *blätter* between blocks that were shoved unequally.

Type II. may, for convenience, be called *faults of vertical thrust*, because the vertical component is large. The type is characteristic of the margins of broad, domical, flat-topped uplifts such as the Marysville batholith and the Bighorn Mountains. The faults are usually intimately associated with flexures. The faults that are of the same kind, orographically, as the flexures, *i. e.*, the faults that add to the height of the uplift and to the depth of the adjacent depression, are named *additive*. These are due to the same forces that elevated the mountain mass. The additive group includes both "thrust" and "normal" faults of the current nomenclature. The complementary group of faults subtracts from the height of the uplift and is therefore designated *subtractive*. They are due to forces opposite in kind to those that made the uplift, probably to gravitative subsidence. All subtractive faults are "normal."

Type III. Tilted fault blocks.—Many great series of step faults are hard to explain by the idea of collapse of an uplift. In some cases the inclination of the strata require that the uplift have a height far exceeding any known elevation on the earth, yet there is no physiographic evidence that such elevations existed. It is more probable that the tilting and faulting of the blocks were concomitant. The hypothesis of continental creep can not explain some of the phenomena.

A suggestion is furnished by a faulted pebble in schist, collected by J. S. Diller. (See U. S. Geological Survey Bulletin 353, fig. 4, p. 22, and *American Journal of Science*, Vol. XXIV., fig. 5, p. 12, July, 1907.) According to Becker the schistose structure is in the final direction of maximum slide, and the oblique faults are in another final direction of maximum slide subordinate to the first. Both were initiated by the same rotational shear or scission, which tilted the oblique faults forward, and which produced practically no change in the direction of the schistose structure.

A cross-section of the mountains of Colorado bears a strong resemblance to this pebble. The schistose structure or direction of greater motion corresponds with the thrust faults and hypothetical buried sheer zones of the mountains. The cross-breaks correspond with the step faults of South Park and the Leadville District. The initial formation of the breaks on the principles of cleavage laid down by Becker, and the subsequent forward rotation of the fault blocks by the same shearing thrust, would explain all the phenomena. In this way both the thrust faults and the normal step faults could be produced at the same time by the same forces.

Quartz as a Geologic Thermometer: FRED. EUGENE WRIGHT and ESPEL S. LARSEN.

On any temperature scale certain temperatures, as the boiling and freezing points of water, are arbitrarily chosen as fixed and standard points of reference. For the geologic temperature scale, similar points must be selected and for this purpose melting points of minerals and mineral aggregates (eutectics), and especially inversion temperatures of enantiotropic forms of the same compound, may serve. Quartz is well adapted to furnish one and possibly two such points, since it has two inversion temperatures, the one at about 560°, where α -quartz inverts to β -quartz, and the second at about 800°, where β -quartz changes under certain conditions to tridymite. Mügge¹ has recently

shown that at 560° quartz changes to a second form called β -quartz, which is also hexagonal and trapezohedral in its symmetry but in all probability hemihedral instead of tetartohedral. This change in symmetry class involves certain changes, as crystal habit, character of twinning and intergrowth of right- and left-handed quartz, and fracturing of crystals, which in turn can be used directly to distinguish quartz formed above 560° from that which has never reached that inversion temperature. These criteria were applied to quartz from 43 different localities, 17 of vein quartz, 13 of pegmatite and 13 of granite and granite porphyry quartz. Nearly 500 plates of quartz in all after the basal pinacoid were cut, polished, etched and tested from these view-points—the net result of the investigation being that the vein quartzes were formed below 560°; also the quartz of certain pegmatites, while all granite, granite porphyry and graphic pegmatite quartzes were probably formed above 560°. By thus fixing temperature limits of formation of quartz, it is possible in many instances to determine limits for other minerals associated with quartz.

The Stream Robbery on which the Belle Fourche Reclamation Project is Based: N. H. DARTON, U. S. Geological Survey.

The Belle Fourche project provides for the irrigation of 85,000 acres of the Great Plains lying north of the Black Hills in western South Dakota. The water is to be taken from Belle Fourche River just below the town of Belle Fourche, carried down the north bank a short distance, and then by a deep cut through a narrow divide to a large reservoir sustained by a long dirt dam. From the reservoir it will be carried by ditches into a large, low-lying basin, where it will be utilized. As in most reclamation projects, the topography presents certain favorable peculiarities. In this case it is that the river near Belle Fourche is considerably higher than the wide basin of tributaries on the opposite side of a narrow divide. This basin was excavated in soft shale by creeks of moderate size. Originally the present river was a very small branch creek, but having greater declivity, it finally cut back through a narrow divide and tapped the headwaters of the Little Missouri River. The river has not yet greatly deepened its valley near Belle Fourche, so that now the water can easily be carried by a short canal system into the large, low lying basin to the north.

¹"Neues Jahrbuch," Fest band, 181-196, 1907.

The locality at which the Little Missouri was tapped, is in the big bend thirty miles northwest of Belle Fourche. Its features are well shown on the Aladdin quadrangle of the U. S. Geological Survey. The former channel is now a flat-bottomed gap through the divide about two miles long and known as Stoneville Flat. To the north it coalesces with the present Little Missouri Valley, while to the south it ends in a cliff of shale eighty feet high descending to the present Belle Fourche River.

At the 214th meeting of the society, held on Wednesday, February 10, under informal communications, Dr. J. W. Spencer presented briefly some "Notes on Borings in the Vicinity of Whirlpool Rapids."

Regular Program

The Pleistocene Phenomena of Southeastern Wisconsin: WM. C. ALDEN.

This paper is based upon detailed surveys of an area of about 8,800 square miles south of latitude 44° N., made under the direction of Dr. T. C. Chamberlin. Outside the terminal moraines of the Wisconsin ice sheet is a deposit of drift regarded as of Illinoian age. The composition of the drift and trend of strata show that the direction of ice movement was, in general, westerly to the limit of the drift. The average estimated thickness over 470 square miles of this area is 45 feet. Very compact reddish till and contorted laminated clays exposed at intervals on the shore of Lake Michigan at the base of the bluff are correlated with this stage of glaciation.

Some, at least, of the vegetal deposits penetrated by wells at many places throughout the area of Wisconsin drift probably represent the Peorian interval of glaciation. To this horizon also may belong the logs and stumps observed by Dr. J. W. Goldthwait near Manitowoc and Two Rivers, Wis. One stump was found still rooted in dense reddish clay provisionally classed with the Illinoian deposits.

The Green Bay, Lake Michigan and Delavan lobes of the Late Wisconsin ice sheet are shown to have been contemporaneous in their maximum extension. Estimated average thickness of drift in the terminal moraine of the Green Bay Glacier at the south end of the lobe is 119 feet (this includes older drift). Along the west side, where no earlier drift is known, the thickness is 61 to 77 feet. The estimated average thickness over 1,611 square miles of the ground moraine, including recessional moraines, is 71.4 feet. Seven-

teen hundred and fifty drumlins of good form occur in the area examined. Evidence is found that some were formed when the ice reached only to one of the inner moraines. Eskers were formed at or near the base of the ice and the esker-forming streams were controlled by the configuration of the drift surface. Direction of movement in the adjacent parts of the two glaciers was almost opposite. The interlobate moraine is 100 to 300 feet high, the relief generally being entirely of drift. Drift of the Lake Michigan glacier estimated as 100 to 150 feet thick at the south, 160 feet at the north and 45 feet midway between. Recessional moraines are well marked.

A readvance of the Lake Michigan glacier covered the moraines east of the Milwaukee River with a deposit of red till southward to Milwaukee. Between Sheboygan and Plymouth this extended 14 miles west of the lake shore. The estimated average thickness of this deposit is 34 feet. In Sheboygan and Manitowoc counties there is a well-marked terminal moraine of red till overlapping the earlier recessional and interlobate moraines. A similar deposit of red till bordering Lake Winnebago indicates a readvance of the Green Bay glacier to the south line of Fond du Lac Township. This readvance is believed to have occurred at the Glenwood stage of Lake Chicago. There is a faint development of the Glenwood beach on the red clay formed when the ice again retreated. This is traceable north through Sheboygan County. In southern Sheboygan County slight traces of a beach occur at the Calumet level. Traces of the Toleston beach occur in Kenosha County, but this was mostly obliterated during the formation of the Nipissing shore, which is strongly marked by cliffs and terraces about 14 feet above Lake Michigan. The Algonquin beach is not distinguishable, possibly it is identical with the Toleston shore. As shown by Goldthwait, there has been little or no deformation of the old shore lines in this area. Filling in the lower part of Milwaukee River valley, consisting of marsh deposits and alluvium extending 50 feet below the level of the lake, indicate that at some time following the Glenwood stage and deposition of the red till the lake waters stood considerably below their present elevation.

Clinton Iron Ores in the Birmingham District, Alabama: ERNEST F. SUBCHARD.

The Clinton formation lies on the flanks of a non-symmetrical anticlinal valley, extending northeast and southwest for about fifty miles, with the city of Birmingham near the middle. Only on

the east limb of the anticline in Red Mountain near Birmingham is the ore of commercial value at present. Northwest of this valley lies the Warrior Field, containing coking coals, while to the southeast lies the Cahaba Field, containing high-grade steam and domestic coal. Cambro-Ordovician dolomite within the valley and Mississippian limestone between the ore outcrop and the coal fields both afford stone for fluxing. The topography is of the ridge and valley type, very favorable for transportation lines to reach the outcrops of ore, stone and coal. The ore is of sedimentary origin. It contains approximately 36 per cent. of iron, 12 to 25 per cent. silica, 6 to 20 per cent. lime and .33 per cent. phosphorus. It occurs in beds like coal, but, unlike coal, the beds are subject to residual enrichment on the outcrop, due to solution of soluble constituents; also they are not so broadly extensive as coal beds. Studies of the strike sections of the ore on the outcrop and of sections at right angles to the outcrop by means of mine openings and drill records show that the beds are long, narrow, lens-like bodies. The quality of the unweathered ore is fairly constant in the direction of the dip. All the facts obtained during recent geological surveys of this field indicate that the ore is the result of original deposition of ferruginous sediments and that, so far as the material continues of workable thickness, it will mostly be found of workable quality.

The Earthquake Rift in Eastern San Luis Obispo County, California: RALPH ARNOLD and H. R. JOHNSON.

This paper embraced a description of some of the topographic features along the earthquake rift and was illustrated by lantern views showing the terraced aspect of the country adjacent to and the offsetting of streams by the rift. An instance of offsetting was described in detail where a stream flowing southwestward from the Temblor Range strikes the rift at right angles, is directed to a northwesterly course along the rift for 400 feet, and finally leaves the rift at right angles and flows off on the plain. The scarp along the rift at this point is on the northeast side, and there is apparently a small alluvial fan developed where the stream leaves the rift on the southwest, so that any hypothesis other than one in which a horizontal movement of 400 feet is assumed does not seem to explain the conditions found here.

PHILIP S. SMITH,
Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 659th meeting was held on January 30, 1909, Vice-president Wead presiding.

The following papers were read:

A Proposed Method for Determining the Solar Parallax: Dr. C. G. ARNOT.

The author cited the recently published values of the solar parallax obtained by observations of the minor planets, and especially of Eros. These generally agree very closely and yield a value $8''.80$ or a trifle higher. The recent long-continued and careful work of Doolittle, on the other hand, has given the value of the aberration constant as probably $20''.51$, corresponding with a parallax $8''.783$. Küstner and Halm have employed the Döppler principle to determine the velocity of the earth in its orbit, by observing the displacements of lines in the spectra of certain stars at intervals of six months. Küstner obtained thereby $8''.84$ for the solar parallax.

The author proposed to use two heliostats and reflect simultaneously on a powerful spectroscope the light of Venus and Mars. A differential velocity of these objects as great as 28 km. per second is available. Adams has in similar fashion determined the velocity of rotation of the sun with a probable error for a single photographic plate of 0.004 km. per second. An experimental photograph of Venus's spectrum has been made with the tower apparatus at Mt. Wilson, on the same scale employed by Adams for the sun, in two hours' exposure. It is thought that a scale of spectrum one fifth as great can be used in practice for a simultaneous exposure on Mars and Venus. By alternating the two heliostats on successive nights, and by carefully reducing the light of Venus to equal that of Mars, and by using a long focus telescope to form the images, so that only the central part of the disks of the planets would be used, the author hoped the method would be capable of yielding in ten nights a value of the parallax accurate to one part in 2,000.

The Magnetic Properties of Iron: Their Application and Measurement: Mr. C. W. BURROWS.

THE 660th meeting was held on February 13, 1909, Vice-president Wead presiding. The following papers were read:

A New Method for Determination of Focal Length: Mr. I. J. PRIEST.

This method, based on the Fabry and Perot interferometer, gives the focal length directly and accurately; it is adapted to lenses of all focal lengths; it can be used for the determination of achromatism; and finally it is unique in that

linear measurement only is involved—a length taken with a micrometer. The use of a costly and cumbersome optical bench is not required. briefly, the method is rapid, precise and convenient. The speaker gave a general account of the theory of fringe formation in the Fabry and Perot interferometer. The several sources of error were considered and all shown to be of the order of one part in one thousand, and hence the error in the determination of focal length f not greater than $f/1,000$.

The Coefficient of Reflection of Electric Waves at a Transition Point: Dr. LOUIS COHEN.

The paper discussed mathematically an important practical question, applicable to many present-day engineering problems, especially to the transmission of power by means of high potential electric currents. It was pointed out that in passing from an air circuit to an underground cable the potential might easily be almost doubled at the point of transition, due mainly to the difference in the capacities of the two parts of the circuit. In the cases of circuits having large localized inductances the potential may at places become nearly double the ordinary line potential. The discussion was in reference to alternating currents.

R. L. FABIS,
Secretary

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND
MEDICINE

THE thirty-second meeting of the society was held at the New York University and Bellevue Hospital Medical College, February 17, 1909, with President Lee in the chair.

Members present: Alsberg, Atkinson, Auer, Banzhaf, Beebe, Berg, Burton-Opitz, Ewing, Famulener, Foster, Gay, Gies, Henderson, Jacobs, Joseph, Kant, Lee, Levene, Levin, Lewis, Lusk, Mandel, Meltzer, Meyer, Murlin, Noguchi, Opie, Pearce, Storey, Terry, Wallace, Weil.

Members elected: John F. Anderson, T. G. Brodie, L. J. Cole, Martin H. Fischer, Richard V. Lamar, Max Morse, Hanz Zinsser.

Officers elected: President, Frederic S. Lee; Vice-president, William J. Gies; Secretary, Eugene L. Opie; Treasurer, Graham Lusk.

Resolution adopted: Resolved, That, on the retirement of Professor William J. Gies from the secretaryship of this society, after a service of six years, the society expresses to him its appreciation of, and its cordial thanks for, his most efficient labors. To Professor Gies's devoted work is due, in great part, the honorable position which

the society has already attained among the scientific societies of this country.

Scientific Program¹

Yandell Henderson: A method for the direct observation of normal peristalsis in the stomach and intestines.

A. I. Ringer (by invitation): Studies on the effects of carbon monoxid poisoning.

George B. Wallace and Hugo Salomon: Intestinal excretion during diarrhea.

R. Burton-Opitz and Daniel R. Lucas: The vascularity of the kidney as influenced by sensory impulses.

Paul A. Lewis: The influence of temperature on hemolysis in hypotonic solutions.

Frederick P. Gay: A carcinoma of the rat (Flexner-Jobling) considered from the standpoint of immunity.

A. O. Shaklee: Influence of temperature upon pepsin.

Nellis B. Foster and James C. Greenway: Synthesis of uric acid.

Hideyo Noguchi: Some critical considerations on the serum diagnosis of syphilis.

D. Manson, L. Kristeller and P. A. Levene: On nitrogenous metabolism in chronic nephritis.

Carl L. Alsberg: The formation of gluconic acid by the olive-tubercle organism and the function of oxidation in some microorganisms.

Jacques Loeb: On the fertilizing and cytolytic effect of soap.

T. Brailsford Robertson and Theodore C. Burnett: On the depression of the freezing point of water due to dissolved caseinates.

W. J. MacNeal, Lenore L. Latzer and Josephine E. Kerr: The daily excretion of bacteria in the feces of healthy men.

Walter A. Jacobs and P. A. Levene: Further studies on the constitution of inosinic acid.

John F. Anderson and M. J. Rosenau: The effect of heat on the anaphylactic properties of proteins.

Charles A. Elsberg: A skin reaction in carcinoma from the subcutaneous injection of human red blood cells.

EUGENE L. OPIE,
Secretary

¹ Authors' abstracts of the papers read before the Society for Experimental Biology and Medicine are published in the *Proceedings of the Society for Experimental Biology and Medicine*. A number is issued shortly after each meeting, and costs twenty cents a copy. Copies may be obtained from the managing editor, Eugene L. Opie, Rockefeller Institute for Medical Research, 66th Street and Avenue A, New York.

THE AMERICAN CHEMICAL SOCIETY
NEW YORK SECTION

THE sixth regular meeting of the session of 1908-9 was held at the Chemists' Club, March 5.

The following papers were presented:

New Aromatic Amino Acids: A. H. KROFFT.

The paper described the method of formation of a certain new diamino isophthalic acid and a diamino toluic acid and of various derivatives of these acids; also some new derivatives of a nitro-amino isophthalic acid and a diamino benzoic acid.

Some New Quinazolines: R. A. GOETNER.

A brief statement was given of further work in the quinazoline field, including some new anthranils and the preparation of some amino and carboxylated quinazolines.

The Determination of Niobium in the Presence of Tantalum.

The process given consists in the reduction of niobium by means of zinc and acid and the subsequent titration with permanganate.

On Tetrachlorether and Dichlorvinylether: WILLIAM FOSTER.

The paper dealt with an improved method for the preparation of tetrachlorether and a new method for the preparation of dichlorvinylether together with the physical properties of these compounds; also with the preparation of ethoxy-chloroacetylchloride by the action of oxygen on dichlorvinylether with a study of the mechanism of the oxidation.

The Industrial Manufacture of Anhydrous Chlorine and the Phenomena Connected with Chlorine Detinning: ELMER A. SPERRY.

The chlorine process of detinning tin plate scrap was described and illustrated by lantern slides and samples. The more important conditions which have made the process commercially successful were set forth. These included the preparation of liquid anhydrous chlorine, the use of a special form of apparatus for regulating the temperature of the reaction, and an electrolytic method for rendering detinned steel free from iron oxide and tin alloy. The tin tetrachloride resulting from the process was shown and its properties, which required special methods of handling, were considered.

The following officers were elected for the session of 1909-10:

Chairman—Morris Loeb.

Vice-chairman—Charles Baskerville.

Secretary-Treasurer—C. M. Joyce.

Executive Committee—W. D. Horne, A. G. Stillwell, C. B. Zabriskie and David Wesson.

C. M. JOYCE,

Secretary

THE AMERICAN MATHEMATICAL SOCIETY

THE one hundred and forty-second regular meeting of the society was held at Columbia University on Saturday, February 27, 1909. The brief program required only a single session. Twenty-four members were in attendance. President Maxime Bôcher occupied the chair. The council announced the election of the following persons to membership in the society: Mr. W. T. Campbell, Boston Latin School; Professor W. A. Garrison, Union College; Mr. D. D. Leib, Johns Hopkins University; Professor William Marshall, Purdue University; Mr. J. B. Smith, Richmond, Va., High School; Mr. C. M. Sparrow, Johns Hopkins University. Ten applications for membership were received.

Professor Bôcher tendered his resignation as member of the editorial committee of the *Transactions*, to take effect August 15, it being his intention to spend the coming academic year abroad. Professor Osgood was appointed to fill the unexpired term.

The following papers were read at this meeting:

Edward Kasner: "Brachistochrones and tautochrones."

D. C. Gillespie: "On extremal curves which are invariant under a continuous group."

Virgil Snyder: "Infinite discontinuous groups of birational transformations which leave certain surfaces invariant."

Professor Bôcher presented certain results in extension of his paper "On systems of linear differential equations of the first order," read February 22, 1902, and to be published in an early number of the *Transactions*.

The San Francisco section of the society also met on February 27, at Stanford University. The Chicago Section meets at the University of Chicago, April 9-10. The next meeting of the society will be held at Columbia University on April 24.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE SCIENCE AND INVESTMENT¹

INTRODUCTION

THE influence of science upon the investment of capital and the employment of labor in productive enterprises is far from receiving its due recognition in systematic economics. There is a vague sort of knowledge that science and productive industry are related much as a handmaid is related to a household. One looks in vain, however, in any of the standard treatises on economics for anything like an adequate appreciation of the place of the natural sciences in that all-engrossing and highly standardized process of production and exchange which makes up the modern system of industry known as capitalism.

One reason for this lies in the fact that the line of approach of the professional economist to the existing system has been by way of politics or philosophy—by inexact and speculative methods, rather than by the more exact methods of experiment and verification. The bias of approach has left its mark in the inconclusiveness of economic discussion, in the lack of agreement as to what is settled and what is not, and even in the question as to what the real scope and aims of economics are. Under the term "progress of nations" we include a complex group of forces. When we come to weigh them out one by one, it will appear that the greatest motive force in the

¹ Address of the retiring vice-president of Section I at the Baltimore meeting of the American Association for the Advancement of Science.

unfolding of material power in modern times has been that of the various sciences. In fact, it is this leavening of our western civilization with the knowledge and power of the natural sciences, in their mastery over the forces of nature in the service of man, that, more than any other single criterion, marks off modernity from all that goes before it.

SERVICES OF GEOGRAPHY AND ASTRONOMY

Historically speaking, the earliest of modern sciences to affect the nature and scope of investment was geography. The European explorations and discoveries of the fourteenth and fifteenth centuries added an area of territory to the field of commerce, probably three times the size of that known to western Europe prior to the rounding of Africa, the opening of a sea-route to India, and the discovery of the American continent. Then followed the formation of the great trading corporations, of which the East India Company was typical. These corporations broadened out into the colonial policies of western Europe, in the effort to exploit the lands thus discovered for the enrichment of the home countries. Thus in the short period of a single century the map of the entire world had changed, almost beyond recognition—all because the science of geography had enabled the researchful spirits of those times to pass from the confines of the known out into the unknown.

The next of the sciences to influence the progress of modern investment was astronomy. It was by the aid of the science of the heavenly bodies that ocean navigation was rendered possible. It is not too much to say that the annexation of the oceans to the world's area of free enterprise was, next to the discovery of America, the one thing that had most to do with making modern nations what they are in things material. On this basis of maritime

traffic, nine tenths of the world's international trade rests. The sea is as vital to Great Britain, and nearly as vital to the national life of Germany, as food is to the body. And yet, without the contributions of astronomy the commerce of the world, which normally among the nations exceeds \$25,000,000,000 a year, would be little more than a coasting trade, whose vessels hug in fear the shores of inland seas and the ocean frontages of their own countries.

These two sciences—geography and astronomy—together put into the hands of man the powers whereby he, within a comparatively short period of time, enlarged the extent of the world's market by three times its earlier area and taught men the art of mastering maritime transportation, thus connecting the world's continents by highways over a field of intercourse covering three fourths of the area of the globe. These sciences, when yet in their infancy, laid the foundations of the commercial, industrial and financial powers whose wealth has since assumed proportions so colossal as to stagger the vividest imagination.

METALLURGY AND THE RÉGIME OF MONEY

The next group of sciences which have radically influenced the course of modern enterprise and investment is that which includes the production and the manufacture of metals. Mining and metallurgy put the old world in possession of the precious metals of the new. The infusion of metallic money in such unheard-of quantities into the economic life of Europe was one of the most revolutionary forces that ever came to any age. There was not a single institution, social relation or business contract that did not undergo radical transformation, by virtue of the effect of the precious metals upon the laborer and the employer, the state and the subject, the debtor and the creditor. The precious metals put the monetary systems of the na-

tions on a metallic basis and thus for the first time gave to them a common standard of international value.

Thus far the three distinct contributions of the sciences to the economic factors that go to make up the modern world market are: (1) The discovery of new lands, (2) the utilization of ocean transportation—the cheapest known and (3) an international standard of value. These three things have determined the plane on which investment activity in its most comprehensive scope is still working out its various problems under the guidance and direction of the sciences of geology, chemistry, physics and engineering.

SCIENCES IN SELECTION AND SUBSTITUTION

Possibly the most signal contribution of geology to the advance of investment is seen in the service which national and state surveys render to the development of natural resources. Each of the American commonwealths now regards such an inventory of the earth's formations and composition as geology alone can give as the indispensable condition of inducing capital to seek profitable employment within its borders. Investment of to-day is itself specialized in such a way that it depends upon the specialist's most complete researches to ascertain beforehand the wisdom or the unwisdom of putting capital of any given amount into an enterprise, as well as of locating it with due regard to the assemblage of the materials of production and to the expenses of marketing the products. Geological data determine in large part the answer to these questions. The state survey of the clays of New Jersey decided the location of a large pottery works at the city of Trenton—a point which had ample beds of the chief raw materials, but which also had the advantage of being half way between two cities of over a million population, yet not a hundred miles apart.

Thus the sciences, besides encompassing the globe to determine where nature has hid her treasures, determines where lines of transportation shall be laid down, where population is destined to concentrate, and in what particular channels of employment both labor and capital may find the maximum returns. In other words, science is a function of economic progress, operating under the law of substitution. According to that law, the fall of the rate of profits impels the producer of commodities to find some less expensive substitute among the articles that make up the elements of the cost of production. In the other direction, the making of extraordinary profits may effectively impel the producer to escape the limitation of supplies which keep him from entering on large-scale production, thus multiplying his profits manifold. The burden of discovering what might serve as economical substitutes falls upon the scientific laboratory.

EVOLUTION OF MACHINE INDUSTRY AND TRANSPORTATION

The chemical and physical laboratory constitute the experimental and exploring arm of the up-to-date industry. The railroad must have it to test its materials. The manufacturer must have it to insure himself, not only against deliveries of inferior materials in contract, but even more so to enable him promptly to test the applicability of any new discovery to his business, to decide as to whether or not there is any advantage to him in changing his methods, and to put to test his finished product before it is sent out, thus detecting any defect in construction which actual use might disclose.

Not only has science made industry and commerce more technical, calling progressively for a more highly skilled and a more varied class of labor and talent, but it has without doubt been the chief factor in differentiating modern industry and com-

merce from the handicraft state in the one case and from the primitive forms of transportation on the other. I put it approximately near the truth in saying that machine industry, meaning all work done by mechanical power, would have been impossible but for the use which has been made of physics, chemistry and mechanics in the evolution of the modern system of production and commercial distribution. These three sciences, for instance, share the honor of achievement in the development of the steel rail on our railroads, from the strip of soft iron strung on a pair of parallel girders to a self-sufficient iron rail resting on cross-ties, into the present-day steel rail weighing 100 pounds to the yard. Here we have chemistry, physics, mechanics and metallurgy working conjointly toward an end, which has in turn become the point of departure for a series of developments in the more economical handling of freight. Cutting down costs and increasing carrying capacity have followed the path along which the sciences have led at every stage, in a railway system now representing an investment of \$20,000,000,000 in the United States alone.

ENGINEERING AND PUBLIC SERVICE

I need hardly remind you that the most rapid strides among investment activities have indeed been made by those in which science has had the largest sway. These are the fields in which engineering has applied the sciences to profitable uses. One's mind naturally turns to the various enterprises in which electrical power has a domain of its own. Communication, illumination and transportation—three fundamental necessities of modern living have opened fields of almost unlimited investment possibilities. In all of them, whether it concerns the telephone or the lighting and power problem, the lines of responsible relations with the public are being

gradually lain down on safer bases. The popular appreciation of mutual approach to common understanding has already been developed in scores of public service corporations, far beyond the needs of public subscription to capital requirements. The very faith aroused in the soundness of these agencies is an asset of no mean significance in proving the profitableness of their investments.

SCIENTIFIC BASES OF LARGE-SCALE INDUSTRY

It is not usually recognized that science puts a premium on the large-scale industry as compared with the smaller undertaking. The latter can not always afford the expense of maintaining experimental work. The advantage would even be doubtful if it could. But with the consolidation of industries under a central management, the scope of scientific possibilities becomes immensely enlarged. Experiments which demonstrate better results for one plant can immediately be appropriated by all. By the exact measurements of methods and results in one establishment the efficiency of all the others can be tested. This indicates one of the ways in which the sciences have contributed toward the concentration of control and the enormous capitalization of the industrial combinations known as the trusts.

Science in this case pointed out the enormous wastes of so large a number of independent establishments, and helped to measure the extent of economies possible under unified control guided by scientific foresight. We may regret the resulting change. We may even fear for the future of popular welfare in a régime of apparently impregnable combinations. But one thing is sure as fate—and that is this: So far as these consolidations are founded upon scientific bases and remain there, their origin, development and future are assured. But so far as they have had an

artificial and unscientific conception, say in the greed of monopoly, and have vaunted themselves with pride of power unbalanced by the laws of nature, to that extent have they implanted in them the seeds of economic death.

Darwin tells us that for survival two factors are necessary—continuity of type and adaptation to the conditions of existence. Now the work of science in the world's evolution of the type of industry which makes for the maximum general welfare is to increase the degree of adaptability so that the historic type may have the greatest facility of adjustment to actual and prospective needs. Size is the condition of survival. But size uncemented by the scientific spirit, unchartered on the sea of enterprise by the directing captaincy of research, is either doomed to wreck or dry rot. The rise of the corporation, in which form free capital now seeks its widest investment, is the outcome of a search for a type of industrial organization in which the science of the laboratory and the savings of the people may be incorporated under responsible management.

FOUR CRITERIA OF CORPORATE SURVIVAL

This brings me to the point of stating the criteria of survival and development to which the modern business corporation must conform. For I think we all recognize that, although under corporate form, the western world has made unparalleled progress in investment, still the main purposes of investment, namely, personal profit and popular well-being, will not, at this stage of the world's democracy, consent to sacrifice the latter wholly for the former. The corporation will survive only as it serves its function of economic progress, both by being a better producer of wealth out of natural resources and by being a better distributor of wealth, once created, as a product of the unified re-

sources of the community. In short, the corporation as an investment institution gathers into itself the surplus resources of the people, on the at least implied promise of bringing them better returns for its use than they can win working alone. The fulfillment of that obligation, whether regarded as moral or legal, is possible only on condition that it meet to a reasonable degree four distinct criteria of business experience.

Investment within each particular field must no longer hazard the certainty of the outcome on individual management divorced from contact with those who furnished the means necessary to bring labor and capital together under responsible control and cooperation. That business management of entrusted capital may enjoy the certitudes of regular returns it must rest upon scientific, not individual, foundations. Thus will investment of popular savings be lifted out of the boggy ways of speculative risks and be raised to the level of demonstration.

First of all, then, the type of investment institution that will meet modern conditions of existence must be *scientific*, in that it must follow the path of demonstrated safety as marked out by scientific research. Secondly, the management of such an institution must be a *responsible* one, in the sense of being morally and technically aware of its rights, duties and possibilities. Thirdly, under existing scarcity of capital the world over, and with the prevailing degree of dependence upon the comparatively small investor, the type of investment organization which prevails will have to be *popular*. It will have to appeal to the confidence of the people effectively enough to draw from them necessary capital, not only for initial investment, but for subsequent doses for extension and development. Fourthly and finally, it goes without saying, that any investment agency

which popular judgment will not destroy will have to be *profitable*.

JOHN FRANKLIN CROWELL

A PLEA FOR TERRESTRIAL AND
COSMICAL PHYSICS¹

ONCE upon a time, at a certain small dinner-party, the Duke of Wellington, on being urged to express his opinion frankly of the French marshals he had so successfully worsted in battle, pointed out their good qualities in a most free and magnanimous manner, showing wherein each particularly excelled. Whereupon one of the party said: "Well, sir, how was it that with such various great qualifications you licked them all, one after another?" The duke, taken back, paused, then said: "Well, I don't know exactly how it was, but I think if any unexpected circumstance occurred in the midst of a battle which deranged its whole plan, I could perhaps organize another plan more quickly than most of them."

This power of being able to instantly change an established train of thought, or to be receptive to a new set of circumstances and facts, and thus to be capable of immediately setting up a fresh plan of action, was tersely and most suggestively expressed by Maxwell. When writing Herbert Spencer about a subject of controversy in the latter's "First Principles," he said:

It is seldom that any man who tries to form a system can prevent the system from forming around him, and closing him in before he is forty. Hence the wisdom of putting in some ingredient to prevent crystallization and keep the system in a colloidal condition.

At the Ithaca meeting of the association, two years ago last summer, I prefaced a paper on the San Francisco earthquake by

¹ Presented at the Baltimore meeting of the American Association for the Advancement of Science, at the general interest meeting of the Section on Physics, December 30, 1908.

a few remarks calling attention to the disparity of papers pertaining to the physics of the earth and of the universe presented to-day before sections A and B. I stated it was my impression that this had not always been the case. Attend any similar meeting abroad, be it in England, Germany or France, and you are apt to find the names of foremost physicists down for papers on results of research in terrestrial or cosmical physics. These eminent investigators evidently find food for exhilarating thought and stimulating work in the unraveling of the phenomena of seismology, meteorology, geodesy, hydrology, atmospheric electricity, solar physics, terrestrial magnetism, etc. They appear to regard knowledge gained in the laboratory and in the university merely as a means to an end, not an end in themselves.

The chairman of the Section of Mathematics and Physics at the recent meeting of the British Association was the well-known physicist-meteorologist, Dr. W. N. Shaw, director of the London Meteorological Office. Besides making a most suggestive presidential address, he led an interesting discussion on "The Isothermal Layer of the Atmosphere"—a live topic in meteorology to-day. Those taking part in the discussion were: Shaw, Rotch, Dines, Cave, Turner, J. J. Thomson, Walker and others. Several times has it occurred within recent years at that association, that, owing to the number of titles presented, it was necessary to have a subsection on "Cosmical Physics" which I am very glad to note did not apparently meet with the favor of the physicists themselves. Our British colleagues want the cosmical physicists to stay with them and not flock off by themselves, and the present tendency seems, accordingly, to be at the British Association, not to form such a subsection. Indeed, Dr. Shaw, in the address referred to, said:

For the advancement of science in this sense we require all three—the professor with academic freedom, to illuminate with his genius any phenomenon which he may be pleased to investigate, the administrator, face to face with the practical problems in which science can help, and the living voice which can tune itself in harmony with the advances of science and in sympathy with the needs of the people whom it serves.

You will find among the past contributors to papers and discussions on the subjects mentioned, such names as, Kelvin, Rücker, Schuster, Lockyer, Eliot, Cortie, Teisserenc de Bort, Glazebrook, Chree, Gill, Thomson, etc.

I can not better illustrate the mutual help that may spring from friendly conference between the pure physicist and the world-inoculated one than to quote you a paragraph or two from a most admirable presidential address delivered by Dr. S. Weir Mitchell, at the second meeting of the Congress of American Physicians and Surgeons, held at Washington in 1891, entitled, "The Early History of Instrumental Precision in Medicine." Referring to this congress of the eminent of the land in medicine and surgery, Dr. Mitchell says:

It is here, therefore, that the open-minded man may feel the broadening influence of intellectual contact with those who have other limitations than his own; for, indeed, in our divergent attention to special studies we run some risk that, contrary to St. Paul, the eye may say to the hand, "I have no need of thee," or the head to the body, "I have no need of thee," for as to us also, there should be no schism in the body. . . .

What the specialist learns, until it is commonplace, is not easily enough assimilated by the mass of practitioners. At last, however, comes a time when it is, and then that whole body of medicine feels the gain in nutrition and repays the debt. The masters of our still most perfect art, medical optics, may wisely remember that it was physicians who most distinctively recognized and diffused the knowledge that headaches and some other brain disorders are due to eye strain, and thus, while lessening our own futile labors, crowded the waiting room of the ophthalmologist. . . .

As I have mentioned the need for continuous

individual cultivation of our multifarious science on a broad scale, and for personal consultation, I like to enlarge the plea and call a meeting like ours a general consultation. And this, in fact, it is; a focal point for condensed opinion, for authoritative statements, for criticism from varied standpoints and for significant indications as to those accepted gains which ought to become, from time to time, a part of the mental equipment of all other special, and indeed of all general practitioners.

Change the words physician, surgeon, medicine, to corresponding ones applicable to this gathering, and what apter or truer characterization of what our own aims and purposes should be could be given than is embodied in these words! One is tempted to wish that we might also, like the "Deutscher Naturforscher und Ärzte Versammlung" of Germany, gather with us in annual conclave the physicians and surgeons as well. Picture to yourselves the opportunities this would afford for enlivening and quickening discussions in several of our sections, and you will appreciate what I am seeking to emphasize, especially here, with regard to open, general meetings between the generalist and the "broadened" specialist. I say "broadened specialist" advisedly, for I believe upon critical examination it will frequently appear that the very pursuit of a speciality has a widening influence not adequately appreciated by one whose sphere of activity is restricted solely within the bounds of his own general science. For there is no more patent and suggestive fact of present-day research than that the most notable and the most rapid achievements are not in the older, well-recognized sciences, but in their borderlands or "twilight zones." Thus the true research worker soon finds it necessary to make excursions into regions beyond what he had been regarding as his own particular zone. He makes new acquaintances, learns new customs and laws and gradually begins to

perceive that there really is no well-defined line of demarcation—like the famous Great Wall of China—between one science or another!

One of the recent fundamental researches on the "Motions of the Moon" has been made by a college professor who, though an American resident, got his chief training and inspiration at Cambridge, England. This same investigator has contributed articles on meteorological mechanics. Columbia University, in its admirable endeavor to present a popular course of lectures on subjects of applied physical science, must draw for its lecture on "Atmospheric Phenomena and Physical Theory" upon another foreign-born, Cambridge-inspired, now American resident mathematical physicist. There are several of you here whose work lends additional eloquent testimony to the broadening and cosmical influence of that eminent school of physics. However, there are other European departments of physics of which much along similar lines could be stated and exemplified. Is it not possible to have more home-inspired university product of our own to draw upon in these fields? Shouldn't we strive that our country be adequately represented on international committees formed to consider and to investigate some of the great world-wide questions? I believe we do not lack the talent. If there is less incentive among us, why is it?

The fact I wish to emphasize is strikingly shown by glancing for a moment at the general character of the programs presented in the first two decades of the association's history before the section on general physical science. The papers classified under physics of the globe, meteorology, geodesy and navigation, frequently exceeded those in physics, chemistry, mathematics and astronomy, whereas now, as you all know, they are in a minor-

ity. Among the authors of the first-named papers we find names which as soon as heard you will identify as among the most distinguished of the college professors of the middle of the last century: Redfield, Bache, Olmsted, Coffin, Alexander, Henry, Silliman, Peirce, Loomis, Espy, Horsford, Guyot, Lovering, Dana, Trowbridge, Mitchell, etc. Among the more eminent of those occupying government positions we find again Henry and Bache, and such men as Maury, Davis, Hunt, Hilgard, Schott, etc. The mental grasp of many of these geo- and cosmical physicists was considered sufficiently broad to make them desirable timber for the highest positions of honor in the association.

In those "good old days" some of the best contributions in meteorology and terrestrial magnetism were made by the college professor. Bache made a magnetic survey of Pennsylvania early in the forties while still a professor at Girard College, where he also established the first magnetic observatory in this country. John Locke, the inventor of the electro-chronograph (which, by the way, is unique in the history of science in this country as being the only scientific invention, I believe, receiving an award from our Congress, viz., \$10,000), in the thirties and forties undertook a magnetic survey of North America with Cincinnati as a base station. He even extended his investigations into Canadian territory and made many of the early observations of the three magnetic elements in the eastern states. Locke was a contemporary of the astronomer Mitchel, holding the chair of professor of chemistry and pharmacy at the Ohio Medical College. He lived at the time when the college professor frequently had to acquire his instruments of research and pay the expenses of his experiments out of his own meager salary. Yet he found ways of doing it and, moreover, had the necessary time to

go beyond his class-room and extend his good work in the territory round about and far away.

Loomis's work on the aurora borealis is still quoted. The contributions to meteorology by Espy, Redfield, Coffin, Maury and Loomis are even known to those of us who do not profess to be meteorologists. These few illustrations must suffice for our present purpose.

If the college professor now lacks the necessary time and incentive during the scholastic year, let him follow the example of Locke, Bache or Nipher who spent their vacations in the open in order to learn something of the physical laws governing natural phenomena. Let him behold his colleagues abroad like Rücker and Thorpe—one a physicist, the other a chemist—who jointly made a magnetic survey of the British Isles during their vacations with the aid of grants which probably just covered expenses and with doubtless no remuneration. The eminent Japanese physicist, Tanakadate, is another instance in point.

Why is it that, in spite of the truly wonderful spirit of research that has literally *seized* us in this country, there are so few of us entitled to be enrolled among those who are making definite contributions to terrestrial and cosmical physics?

We note with pleasure that the American physicist is very prominently represented, indeed, in astronomy and astrophysics. May we not hope that he will soon realize that this planet on which we dwell, and which must form the basis of all our astronomical speculations, is also worthy of the highest and most unselfish devotion? That, indeed, to reap the full and most lasting benefit of our celestial researches we must keep equal pace with our terrestrial ones? Let him recall that nearly every one of the great physicists

has at one time or another extended his mental vision beyond the problems immediately before him and considered what the application of his laboratory discoveries might be towards solving some of the riddles of the universe, or how he might benefit mankind. Faraday, Maxwell, Kelvin, von Helmholtz, Hertz, Mascart, Langley and Rowland are but a few of the inspiring names.

Happily, there are already some indications of a reawakening, and we note with pleasure the example recently set by our retiring president, who turned his sabbatical year to fruitful use in the study of some perplexing atmospheric phenomena. We note movements at some of our large universities to expand their graduate courses in the direction of the applied science here had in mind. At the present meeting we find 12 papers before Sections A and B, which might properly be classified under terrestrial and cosmical physics.

Von Helmholtz, as many of you know from actual experience, was a notoriously poor lecturer. He seemed utterly incapable of imparting his vast knowledge in any systematic manner, and doubtless the chief value which his listeners got was the inspiration imparted by class-room association with this gifted man. Von Bezold, who delivered the Berlin memorial address on von Helmholtz, told me the latter gave as the reason of his inability to impart his acquired knowledge methodically, the fact that he himself had not gained it in that way. He would take up his mathematics, for example, only when he required it—not by going systematically and consistently through a volume of higher analysis without some impelling or suggesting motive. And so it was with the other sciences with which he had to familiarize himself to push to successful completion an intricate and complex piece of research. Yet how

truly marvelous was the grasp this man displayed in so many varied subjects!

Now who has ever attempted to apply his knowledge to fields outside his own immediate one that has not felt this same irresistible, impelling, burning desire to know all that has been done before him in the new country he is about to explore? Haven't we each one of us found that with such an all-conquering impetus back of us the most complex mathematics or the most abstruse subject teems with a new and living interest? What was irksome before has now become a pleasure! And if there is one of you who for lack of excursions into such green pastures has not had new and invigorating blood course through his veins and has not been given a glimpse of a higher, truer and more ennobling vision of life, he has missed the greatest pleasure and the highest compensation open to the research worker!

Do you know of a school of thought that has prevailed for any length of time without resistance to that most subtle and, therefore, most dangerous of all insidious modes of attack, viz., the one coming from within its own fold of devotees, due to the pernicious habit of in-breeding? Is there any greater danger than that which besets a university which fills its chairs repeatedly from among its own graduates? We all know of the fallacy of the brilliant professor who thinks his ideas can be made to continue longest by surrounding himself with assistants drawn, if not entirely, at least chiefly, from among his own disciples. Will he not surely find, as Maxwell put it, that his "system has closed him in before he is forty" because he has forgotten the essential element to prevent crystallization—the importation of fresh blood and the introduction of new ideas?

If you agree with the speaker thus far, may not similar occurrences be recorded of our societies, because of the suicidal policy

of a particular class of members who are apt to believe that the best result can be reached by increasing their representation, and thus by their majority vote be able to dictate and control the general policy of the society to which they belong? Is it wise organization for membership in any deliberative body to be so constituted as to make it possible for the act of the assembly to be unduly influenced by one set of investigators? Is there not here subject for careful thought—a source of degeneracy due to the in-breeding in societies to be equally guarded against? Joseph Henry truly said: "Votes in science should not be counted, but *weighed*!"

This then is my specific plea: a broader conception and a more scientific representation of the subjects of physical research. Could we not make the attempt certainly once a year to devote most of our time and attention to some of the greater aspects of our work and take stock, so to speak, of our achievements, and of their possible applications?

L. A. BAUER

REPORT OF THE COMMITTEE OF THE AMERICAN CHEMICAL SOCIETY APPOINTED TO COOPERATE WITH THE NATIONAL CONSERVATION COMMISSION

In May, 1908, a meeting of the governors of the different states was held at the White House in Washington to consider the conservation of our rapidly wasting natural resources. Following this meeting, a commission was appointed by the president of the United States to investigate the subject, and the principal scientific societies of the United States were invited to cooperate with it. The committee of the American Chemical Society, appointed in response to this invitation, now has the honor to submit the following preliminary report.

On December 8, 9 and 10 the National Conservation Commission met in Washington in joint conference with the delegates of

other organizations and the governors of more than twenty states. The commission, in its elaborate investigations, had, so to speak, taken stock of our natural resources, and its report, therefore, was essentially statistical in character. It had estimated the magnitude of each particular resource, and had studied the rate of consumption of such substances as lumber, coal, iron, etc. It discussed the wastage of the land by preventable erosion, and its effects not only upon agriculture but also in reducing the navigability of streams. Questions like these were treated at considerable length, and their general character is all that need be mentioned just here. The data of the commission were mainly classified under four headings, namely, minerals, forests, lands and waters, and under each one the evils to be remedied were pointed out with all the emphasis and clearness which the statistical method of investigation made possible. The commission cleared the ground for study into the prevention or limitation of future waste; and the problem of conservation can now be taken up in a more intelligent manner than has been possible hitherto. We now know better than ever before what the evils and dangers really are; the next step is to discover remedies, and then, finally, to apply them. The public attention has been aroused; the people of the country are awakening to the necessity of greater prudence and economy in the use of our resources, and definite lines of action can now be laid down with a reasonable probability that they will be followed. Fortunately the reports of the commission are neither sensational nor unduly pessimistic; the results of their conferences are presented seriously, and in such a manner as to compel consideration; they are therefore all the more likely to produce permanent effects of great benefit to the American people. The utterances of the mere alarmist rarely carry conviction; but disclosures like these made by the Conservation Commission can not be disregarded.

Up to the present moment chemistry has had little to do with the investigations of the commission. Henceforward the chemist must

be called upon in many ways, for the waste of resources is often preventable by chemical agencies. Chemistry has already done enough to prove its potency, and its influence is felt in every branch of industry. Adopting the classification of the commission, we shall find the chemist active under every heading. Under minerals, we must note that metallurgy is essentially a group of chemical processes by which the metals are separated from the ores; a separation which may be either wasteful or economical. Within recent years, within the memory of members of this society, the available wealth of the world in metals has been enormously increased. By the cyanide process for extracting gold, ores are now profitably worked which were formerly worthless, and at the same time the demand for mercury has been decreased. The Bessemer process for steel making, now also modified for use in copper smelting, is purely chemical; and its later modification, the Gilchrist-Thomas process, applies similar principles to phosphatic ores, which were previously of little value. Furthermore, in the last-named process, phosphatic slag is produced, which is useful as a fertilizer and helps to relieve the drain upon our rapidly wasting supplies of phosphate rock. Chemists are now studying, with much success, the problem of preventing corrosion in iron, a research which will prolong the life of iron structures and thereby reduce the waste of ore. The use of coal slack by briquetting methods is largely based upon chemical investigations; the salvage of by-products from coke ovens, such as tar and ammonia, is wholly due to chemical research; coal is further economized by the study of boiler waters and the consequent prevention of boiler scale. Even inferior coals, lignites, are now converted into what is known as producer gas, and so are transformed into the best kind of fuel. Petroleum is refined by chemical means, and every fraction of it is saved, either as illuminating oil, as gasoline, as a lubricant, as vaseline, or as paraffin. These are all notable achievements, but greater are yet to come. Enormous quantities of valuable substances are thrown into

the atmosphere in fumes from smelters, which should, and probably can be, partly saved. Electro-chemistry is rapidly developing a large group of new industries, making such metals as aluminum, magnesium and calcium available for use, and it is reaching out into other fields of electrometallurgy in which electric heat, generated by water power, will be used for smelting other metals, thereby reducing the consumption of coal.

In forestry also, the influence of the chemist is distinctly felt. The sprays, used for destroying noxious insects, are chemical preparations. The manufacture of wood alcohol is a chemical process, which may be either wasteful or economical. Turpentine is now produced wastefully, but the waste can be diminished by careful refining, and furthermore, the chemist can aid in discovering substitutes for it. Substitutes for tan bark are also to be sought for by means of chemical investigations. Another distinctively chemical operation is the preparation of wood pulp for paper making, a process which is now wasteful in the highest degree. It is estimated that for every ton of pulp now made by the sulphite process more than a ton of waste material is allowed to drain away into our streams. How to make this material useful is a chemical problem, and so also, in great part, is the investigation of other, now useless fibers, which may replace the more valuable wood. The preservation of wood from decay is still another art in which chemistry is predominant.

In preserving the fertility of our land, chemistry has an important part to play. Our knowledge of fertilizers, of the food on which crops can thrive, is entirely chemical so far as accuracy is concerned, and must be applied in accordance with chemical principles. A fertilizer which is useless, and therefore wasted on one soil, may be needed on another. Certain fertilizers, like the Stassfurt salts, Peruvian guano, the Chilean nitrates, and phosphate rock are limited in quantity, and their future exhaustion must be considered now. What shall replace them in the future? Already processes have been devised for fixing

the nitrogen of the atmosphere and rendering it available for plant food. Saltpeter and other nitrates can be and long have been made from waste materials such as old mortar and animal refuse. The phosphatic slags have been mentioned in connection with metallurgical processes. These sources of fertility are important, but greater still is the source found in our municipal sewage. The problem of its salvage has been worked out in some localities, but in the United States the people are only beginning to be aroused to its importance. Enormous masses of material, easily available for fertilizing purposes, now drain into our rivers or directly into the sea. Another question, now under investigation, is the possibility of using our common feldspathic rocks in fine powder, to replace the potassium withdrawn by plants from the soil. The relations between the chemical composition of water and the conservation of natural resources are of intimate and fundamental importance and some of them have been mentioned under other headings. The rate at which the land surface of the United States is being transported to tide water has recently been estimated by means of chemical analyses of river water coupled with determinations of stream flow, and the results of the computations will doubtless assist considerably in studying soil erosion and the impoverishment of agricultural lands. In steam making the chemical quality of the water supply is an appreciable factor in fuel consumption, a subject to which reference has already been made. The scale that forms on the boiler shell and tubes, when water containing incrustants is used, is a poor conductor of heat and, consequently, causes increased expense for fuel. By detailed study of the chemical composition of available boiler waters, it is possible to select a supply having a minimum amount of incrusting, corrosive and foaming constituents, thereby effecting appreciable economy in fuel. Chemical investigation of methods for purifying water supplies, not only for boilers but for paper manufacture, soap-making, and other great water-consuming industries, will enable man-

ufacturers to make new and greater saving in many raw materials other than fuel.

Stream pollution by industrial refuse and by sewage is a source of enormous waste in our natural resources. The subject has been for many years a field of research for industrial, sanitary and biological chemists in the United States, and their investigations have resulted in the improvement of manufacturing processes, the utilization of wastes, the purification of sewage, and the protection of domestic water supplies. When the presence of deleterious substances in our river and lake waters has caused loss of fish life and the destruction of oyster beds, the chemist and the biologist have detected the harmful ingredients and have suggested methods for their removal. River silt, an important source of detriment to navigation, is also estimated by the chemist. It has been fully demonstrated that the prevention of stream pollution lies not alone through injunctions and other legal proscriptions but also in using waste materials or, when that is not possible, in rendering them harmless. The chemist has much to do in protecting and preserving the quality of our water supply. Upon that, in very great measure, depends the preservation of our highest resource, human life. Polluted waters distribute typhoid fever and other dangerous diseases, and so cause losses which should be, and really are, preventable.

The foregoing illustrations are enough to show, for present purposes, the intimate connection between chemistry and the study of conservation. They also bring out the fact that the classification adopted by the national commission, although admirable for statistical research, is not final, and that it needs to be supplemented by a different subdivision of the data. The facts to be investigated often fall under more than one heading of the classification, and actually interlock in every conceivable manner. To operate a placer mine, for example, abundant water is needed, while a deep mine requires timber for its shafts and levels. In building and occupying a house one covers land, uses lumber, brick, stone, and iron, introduces water supply, and burns fuel.

In short, every phase of the conservation question affects the interests of everybody. If the investigation of our natural resources is to be made effective, it must be applied to individual industries, and in order to do that another scheme of classification would seem to be necessary. Such a scheme we venture to outline, but very briefly.

At the outset the problem can be divided into two parts, one relating to sources of energy, the other to material substances. The two are not really separable, but may advantageously be considered separately.

In the first place, the energy available for industrial uses may be classified under three heads, as follows: First, *inexhaustible energy*, such as solar radiation, wind power, tidal power and, with certain limitations, the power furnished by flowing streams. Second, *reproducible or renewable energy*, like the power supplied by horses and other domestic animals. Wood, regarded as fuel, also falls under this heading, for forests can be artificially grown. Third, the *exhaustible energy* represented by mineral fuel, like natural gas, petroleum, and coal, which, once used, is gone forever. Under this classification the practical problems are, to economize the exhaustible energy, to encourage the development of renewable energy, and to discover new methods of using the inexhaustible energy.

Exactly the same classification applies to material substances. Some, like sea salt, limestone and clay are, humanly speaking, *inexhaustible*. Agricultural and forest products are *reproducible*, some of them year by year. The metallic ores and such useful minerals as phosphate rock are, however, *exhaustible*, and need to be conserved.

With the aid of this very simple classification it becomes possible to analyze a specific industrial problem in such a manner as to make evident its factors of waste or economy. For example, sea salt is *inexhaustible*, and may be extracted by solar evaporation, which is a use of *inexhaustible energy*. Agricultural products are *renewable*, and their production chiefly requires the *renewable energy* of men and animals. But the smelting of

metallic ores, as now conducted, involves the use of exhaustible material both as ore and as fuel.

In most industries, however, the two sets of considerations are combined. Portland cement, for example, is made from inexhaustible substances, but is burned with exhaustible fuel. The latter factor in the industry, therefore, is the one to be carefully considered, while the first factor is negligible. Taking industry by industry we shall find that this condition of affairs is general, and that each one must be studied by itself with reference to its inexhaustible, reproducible and exhaustible elements. In doing this a clear notion can be obtained as to the real needs of a given industry, and our attention can then be concentrated upon those features of it which particularly demand economy. We shall be able to locate evils with greater accuracy; to diagnose the industrial diseases, so to speak, and then to look intelligently for remedies. Many of the remedies must be sought for along chemical lines of research, which will develop economical processes of manufacture, utilize materials that are now wasted, or substitute cheap for costly substances. Cheap and costly, however, are words which need qualification. A substance or a process which is cheap to-day may be in reality wasteful with a temporary reduction in price at the cost of some permanent economy. For our purposes the two words imply a deeper discrimination than is carried by their ordinary use. Temporary efficiency and cheapness are to be discountenanced, while permanent economy for the benefit, not only of the nation but of the whole human race, is to be encouraged. This principle is sound, but its practical applications will involve many difficulties, and develop many conflicts with special interests. Like all ideals it can not be realized absolutely, but it represents a standard of action towards which we must move, even though the ultimate goal of perfection may never be attained. Evils can be mitigated, although they may not be entirely removed.

The American Chemical Society now num-

bers more than four thousand members, scattered through all the states and territories of the union and represented in every one of our great productive industries. These chemists are at the same time progressive and conservative in their work, for they are both discovering new utilities and protecting old ones from loss. We believe that every member of the organization is necessarily in sympathy with the great forward movement for economy, and that in our society the National Conservation Commission will find a most powerful and willing ally.

SCIENTIFIC NOTES AND NEWS

THE Royal Academy of Stockholm has presented Mr. Thomas A. Edison with its Adelskiöld gold medal for his inventions in connection with the phonograph and the incandescent light. This medal is conferred once in ten years.

PROFESSOR CLEVELAND ABBE, of the U. S. Weather Bureau, has been elected an honorary member of the Royal Meteorological Society.

THE Alumni Association of Columbia College and the School of Mines gave a dinner to Dean J. H. Van Amringe, professor of mathematics in Columbia University, on April 3, to celebrate his birthday and a half century of teaching at Columbia College. A loving cup was presented to him.

It is announced that President Taft has requested Surgeon General Wyman to draw up a tentative plan for the consolidation under one bureau of the agencies exercised by the federal government for the preservation of the public health.

M. JUNGFLEISCH has been elected a member of the Paris Academy of Sciences in the section of chemistry as successor to the late M. Ditte.

MR. CHARLES S. SHERRINGTON, professor of physiology in Liverpool University and Mr. William H. Maw, editor of *Engineering*, are

to receive the doctorate of laws from Glasgow University.

THE Chemical Society, London, has conferred its Longstaff medal on Professor S. F. Kipping, of University College, Nottingham.

PROFESSOR HAROLD DIXON has been elected president of the Chemical Society, London, succeeding Sir William Ramsay.

At the sixty-second annual meeting of the Paleontographical Society, held in the rooms of the Geological Society, London, on March 19, Dr. Henry Woodward was reelected president, Dr. G. J. Hinde, treasurer, and Dr. A. Smith Woodward, secretary. Sir Archibald Geikie, was elected a vice-president in succession to the late Mr. W. H. Hudleston.

PROFESSOR THOMAS PURDIE will retire at the end of the summer session from the chair of chemistry at St. Andrews, owing to ill-health.

THE Isaac Newton studentship at Cambridge University, tenable to April 15, 1912, has been awarded to Mr. W. J. Harrison, of Clare College.

MR. N. W. THOMAS has been appointed government ethnologist to southern Nigeria.

DR. CAROLINE MCGILL, instructor in anatomy at the University of Missouri, has been awarded the Sarah Berliner research fellowship for women of the value of \$1,200.

DR. PHILIP P. CALVERT, assistant professor of zoology in the University of Pennsylvania, will be given leave of absence, and his place will be filled next year by Dr. Merkel Henry Jacobs, who is now engaged in post-graduate study at the University of Berlin.

MR. J. R. JOHNSTON, of the Bureau of Plant Industry, returned recently from the vicinity of Baracoa, Cuba, where he has been engaged for some months in researches on the nature and possible control of the cocoanut bud-rot.

DR. VICTOR C. VAUGHAN, of the University of Michigan, will deliver the presidential address at the meeting of the Association of American Physicians to be held in Washington on May 11 and 12.

DR. A. C. LANE, state geologist of Michigan, gave a special lecture on "The Grain of

Rocks," in the department of geology and a talk on the "First Evidences of Life on the Globe," to the Science Club, at the University of Wisconsin on March 26.

At the meeting of the American Philosophical Society on March 19, Professor Marston T. Bogert, of Columbia University, gave an address entitled "On Coal Tar Products and their Application in the Arts and Medicine," which was illustrated by a large number of specimens.

MAJOR M. W. IRELAND, who is chairman of the committee appointed by the legislative council of the American Medical Association, to assist Mrs. Carroll, the widow of Major James Carroll, announces that \$2,500 have been subscribed, chiefly by medical officers of the Army, the Navy and the Public Health and Marine Hospital Service. Though Mrs. Carroll was voted a pension of \$125 a month, this does not suffice to support and educate her seven minor children; the aged mother of Major Carroll was also dependent on him. Subscriptions for the relief of Major Carroll's family and as a recognition of his heroic and distinguished services for the suppression of yellow fever may be sent to Major M. W. Ireland, Office of the Surgeon General, War Department, Washington, D. C.

DR. WILLIAM JONES was murdered, on March 28, by natives in the Philippine Islands, where he was carrying forward anthropological work on behalf of the Field Museum of Natural History of Chicago. Dr. Jones, who was partly of Shawnee Indian descent, studied at Harvard University and subsequently took the degree of doctor of philosophy at Columbia University. He was an accomplished anthropologist, and his death is a serious loss to the science of anthropology.

WILLIAM CHARLES KERNOT, professor of engineering in Melbourne University, has died at the age of sixty-four years.

FOLLOWING up the plan inaugurated by the section of geology and mineralogy of the New York Academy of Sciences last year, the mineralogical and geological section of the Academy of Natural Sciences of Philadelphia proposes to arrange for a second annual spring

meeting of the geologists of the northeastern United States, to be held in Philadelphia on Friday and Saturday, April 23 and 24, 1909. It is planned to hold two sessions for the reading of papers, and a field trip to typical localities of the Pre-Cambrian and early Paleozoic rocks of the region. It is hoped that every one will be able to contribute, if not an extended paper, at least an informal account of work being carried on. Titles should be sent to Professor E. T. Wherry, Lehigh University, South Bethlehem, Pa.

On Thursday evening, March 18, Dr. Barton W. Evermann, assistant in charge of scientific inquiry, Bureau of Fisheries, Washington, D. C., delivered a lecture to the members of the Massachusetts Fish and Game Protective Association and their invited guests at the Copley Square Hotel in Boston. His subject was "With Packtrain to the Tip-top of the United States in Quest of the Golden Trout," illustrated by numerous stereopticon slides. When it was reported to President Roosevelt that the golden trout, known only from Volcano Creek in the High Sierra of California, was in danger of extermination, he called upon U. S. Fish Commissioner Bowers to have an investigation made and Dr. Evermann was put in charge of the field party. The golden trout of Volcano Creek proved to be an undescribed species which has been named *Salmo roosevelti*. Another undescribed species was found in Soda Creek, a western tributary of the Kern; and it has been named *Salmo whitei*, in honor of Stewart Edward White, who suggested the investigations. The expenses of the lecture were paid from the income of the "Ivers Whitney Adams Fund," a gift of \$5,000 presented the association in 1908, by Mr. Ivers Whitney Adams, of Boston, "to secure and provide lectures to be given before the members of said association at regular or special meetings of each year, but not at annual banquets, said lectures to be illustrated, as far as practicable, and connected with the objects of the association."

The *Geographical Journal* states that in 1907 Professor Eberhard Fraas discovered an interesting fossil bed in the Upper Cretaceous formation of Tendagur, in the Linde district

of German East Africa. This deposit contained a number of bones of Dinosaurs, the bones of these huge reptiles lying for the most part in their natural position in the marl and sandstone, from which they have weathered out so that they protrude at the surface. The specimens brought back by Professor Fraas are now mounted in the museum at Stuttgart, and have been shown to belong to a herbivorous Dinosaur which must have reached a length of about 48 feet, and has been named *Gigantosaurus*. The specimens are incomplete, and so much interest has been aroused by them that the German government has decided to send a special expedition to the region, to examine the deposit in detail, and to make additional collections of fossils.

The honorary secretaries of the Zoological Society of Scotland, which has recently been founded, inform *Nature* that the society has been formed for the purpose of establishing a living zoological collection and garden at Edinburgh. The garden will be arranged on the system adopted by Herr Hagenbeck, of Hamburg, and will be conducted on scientific lines. When the society has developed sufficiently, it is within its scope to establish branch gardens in the other large towns in Scotland. In addition to this, lectures of a popular nature by eminent zoologists will be arranged. The headquarters of the society, and the first and principal garden, will be at Edinburgh. To obtain the necessary capital a garden fund has been opened, to which donations are solicited. The annual subscription is £1 1s., but members who join the society during 1909 pay 10s. only for that year. This will entitle members to all the privileges usual in such a society. The aim of the promoters is to build up a strong society with a large membership, so that a considerable part of the annual sum required for the upkeep of the gardens will be insured from subscriptions, and less dependence will require to be placed on the receipts from the public for admission.

At the regular monthly meeting of the Biological Club of the Ohio State University on Monday evening, March 1, a special program in commemoration of the centenary of the birth of Charles Darwin was presented.

President William Oxley Thompson had consented to act as honorary chairman, but later found it impossible to be present, and Miss Freda Detmers, president of the club, presided. The program was intended to cover the various phases of Darwin's life work as the following list of subjects will indicate: "Darwin's Character and Method of Work," Professor F. L. Landacre; "The Influence of Darwin's Work in Geology," Professor G. D. Hubbard; "Darwin's Contributions to Zoological Science," Professor Herbert Osborn; "Darwin in His Relationship to British Stockmen," Professor C. S. Plumb; "Darwin's Contributions to Horticultural Science," Professor V. H. Davis; "The Work of Darwin in Physiological Botany," Professor A. Dachnowski; "Darwin's Contributions to Botany," Professor J. H. Schaffner; "Darwin and Modern Philosophy," Professor A. E. Davies; "Darwin and Modern Psychology," Professor D. R. Major.

UNIVERSITY AND EDUCATIONAL NEWS

THE appropriations committee of the Pennsylvania House of Representatives has reported a bill recommending an appropriation of \$700,000 to the University of Pennsylvania.

It is said that Dalhousie University is likely to be removed from Halifax, N. S., to the city of Dartmouth on the opposite side of the harbor. This city has offered a free site and about \$100,000 for buildings.

THE governor of Colorado has signed a bill permitting the state university to conduct the last two years of its medical course in the city of Denver.

THERE has been introduced in the New York assembly a bill which provides that five members of the board of trustees of Cornell University shall be appointed by the governor, his appointments to be subject to the approval of the senate.

A ROYAL commission has been appointed to consider the position and organization of university education in London.

THE inauguration of Dr. Richard C. MacLaurin as president of the Massachusetts In-

stitute of Technology will take place on Monday, June 7, at Symphony Hall. A committee of the corporation, faculty and alumni has been appointed to take charge of the ceremony.

MR. R. H. WHITBECK, of the New Jersey State Normal School, Trenton, N. J., has been appointed assistant professor of geology at the University of Wisconsin. He will give courses especially intended for the preparation of teachers, dealing primarily with applied geography and with materials available for secondary school teaching and methods of presenting physical geography, geography and geology.

DR. EDMUND LANDAU, docent at Berlin, has been appointed professor of mathematics at Göttingen.

DISCUSSION AND CORRESPONDENCE

CITY BOYS VERSUS COUNTRY BOYS

TO THE EDITOR OF SCIENCE: In your issue of February 12 Mr. W. J. Spillman, under the title "Education and the Trades," makes, with regard to the birthplaces of leading Americans, the following surprising statement:

I believe there are some things which have higher pedagogic value than anything taught in our schools to-day, else why is it that with only 29 per cent. of our population actually living on the farm, with miserably poor school facilities as compared with our city population, this 29 per cent. furnishes about 70 per cent. of the leaders in every phase of activity in this country?

I say surprising, because any one who is familiar with modern investigations in the inheritance of mental qualities in man, must see that such a supposition, if it were indeed a fact, would seriously clash with the conclusions drawn from a number of researches otherwise harmonious and mutually supporting.

This point I will discuss later, but now let us test the facts. Does the farm produce more than its share of leading Americans? Such a question must be answered on a statistical, impartial, and as far as possible, scientific basis. It is first necessary to determine who are the "leaders in every phase of activity in this country." I have turned to "Who's

Who in America" to answer this question. This book has already been successfully used in several sociological studies, and has great value as a starting point for such researches. The editor doubtless tries to be as impartial and comprehensive as possible; but its greatest value to one who wishes to answer a question similar to the present discussion, is that here he finds a list of names prepared by some one else, without any idea or bias in relation to the investigator's present problem. Thus the first, and one of the most important requirements is obtained, the subjective element is eliminated.

Some will not be willing to accept conclusions drawn from a list which like this doubtless has certain flagrant omissions, and where he sees names that he considers should not have been included. If he will stop for a moment and think, he will see that the very objection he raises only argues in the other direction from what he supposes. If, for instance, I find a marked correlation between city birth and more or less notable subsequent achievement, drawn from an imperfect list, the correlation would be even higher were the list of names ideally perfect.

In "Who's Who in America" the birthplaces are given in nearly every instance, although they seldom enable one to differentiate between farm or village. This difficulty can, however, be overcome by making the question one of urban as against non-urban nativity.

The leaders of to-day are about fifty years old on the average, so we must go back a half century and picture American population as it was then distributed. According to the census of 1860, there were 5,072,256 persons living in cities of over 8,000 inhabitants, out of a total population of 31,443,321, or 16.1 per cent. This standard of 8,000 or more is the one arbitrarily taken by the census bureau as constituting a city, and is so used to illustrate the growth of urban populations. There were ninety-six such cities, and a list of them is given in the "Annual Cyclopaedia" for 1861. It is easy then to see if these cities have done better or worse than might be expected in producing leading men. Under initial A in "Who's Who in America," we

find 128 born in cities out of 433, or 29.6 per cent. as against the 16.1 per cent. expected.

Under initial B, we find 404 out of 1,477, or 27.5 per cent.

Under initial C, we find 362 out of 1,143, or 31.7 per cent.

Under initial D, we find 213 out of 676, or 31.6 per cent.

Under initial E, we find 97 out of 273, or 35.6 per cent.

For the sake of being on the safe side I have added all the unrecorded birthplaces to the suburban and rural, and yet the latter fail to produce their proper quota in every single group, and in fact every little group of fifty or a hundred taken at random alphabetically will show the same result.

It seems unnecessary to carry investigation further to establish the fact that the urban beats the non-urban by nearly two to one. The towns, villages and farms should have produced more than five times as many leaders as the cities. They have failed to produce more than about twice as many. Thus the entire non-urban which should have given rise to about 85 per cent. of the total has only produced about 70 per cent. As a great many persons are recorded as born in towns or villages, it is evident that the number from actual farms must be considerably under Mr. Spillman's 70 per cent., at least as far as the evidence drawn from this book is concerned. The inference is that since the cities beat the non-urban districts as a whole, the towns and villages would make a proportionately better showing than the farms, were the necessary data given.

Now, as to its bearing on the question of heredity. It is an easily verified fact that talent tends to be drawn by, and to locate itself in the great centers of human activity. If we turn to the geographical index in the back part of our same biographical reference volume, we find that the great cities, New York, Chicago, Boston, etc., show two or three times as many names as would be expected merely from their populations. I think no one will question the fact that there has been a migration and selection of the most able men, especially the ambitious and gifted young

men, towards the large cities and away from the small towns and farms. This change is in process at present, and must have been going on for some time. Thus there is every reason to suppose that by the year 1860 (if not very much earlier than this) there had already taken place a part at least of this same phenomenon. So that the distribution of talent was then somewhat as it is to-day, concentrated about the cities.¹ Now if mental traits are inherited, the cities must show a higher proportionate birth of talent than the country, and our observed facts are only what we might expect.

Of course it is impossible here to separate the question of environment, which may be more favorable in the city, as some contend, or less favorable, as others sometimes think, or be the slight and almost unmeasurable force which I, myself, shall be content to hold it, until some one has succeeded in measuring it.

Mental heredity, on the other hand, has been measured, and the results are in substantial agreement.²

It is not the purpose of the present communication to present these figures from "Who's Who" as a proof of heredity, but only to point out that there is nothing in the distribution of the birthplaces of leading Americans to conflict with the strongest belief in the force of inheritance, should one happen to have gained such a belief from other sources.

SCIENTIFIC BOOKS

The Principles of Mechanics for Students of Physics and Engineering. By HENRY CREW, Professor of Physics in Northwestern University. 8vo, 295 pp. New York, Longmans, Green & Company. 1908.

This book represents a course which Professor Crew has given for several years at Northwestern University to students intending to specialize in physics and in engineering. The students have had a class and laboratory college course in general physics and more or less work in elementary calculus. Professor Crew states in the preface that his purpose is "to lead the student to clear dynamical views in the shortest possible time without sacrificing him upon the altar of logic, yet pursuing a route which he can afterwards follow with safety." The plan is to confine the treatment "to that part of mechanics which is common ground for the physicist and the engineer" (again quoting the preface). The general dynamical principles involving advanced calculus and analysis are accordingly not included. There are six chapters, one on kinematics, two on kinetics, one on friction, one on elasticity and a short chapter on fluid motion. As the title of the book indicates, the principles are emphasized rather than the applications. In making such a book, every one will, of course, have his own ideas as to topics to be included and those to be omitted. Professor Crew's book represents a course of the essentials, which has been selected after actual classroom experience. An excellent feature is the attention given to rotational dynamics, a part of mechanics on which many text-books are weak. The "illustrative problems" and "examples for practise" scattered through the book are very simple, avoiding involved analyses and calculations.

While the book is intended both for students of physics and of engineering, we believe it will appeal more strongly to the student of physics and this is not so much in its subject-matter as in its temper. For the general student, the purpose of the book is admirable—namely, to take the student in the

second year of his work in physics, immediately after the completion of a course in general physics, and to give him a thorough course in the principles of mechanics stated in the language of the calculus and vector analysis, but emphasizing the physics of the subject. The statement of physical facts and concepts in mathematical language is one of the difficult steps in a student's course; and Professor Crew has done well in giving us his introductory course in the mathematical side of physics.

The book is written in a style which is always clear and interesting. The forms of statement are fresh, and the author has drawn on a wide range of reading and experience for new and apt illustrations.

A. P. CARMAN

The Evolution of Forces. By GUSTAVE LeBON. Pp. 388. New York, D. Appleton & Co. 1908.

In the controversy between Mr. Norman Campbell, of Trinity College, Cambridge, and Mr. F. Legge, of the Royal Institution, concerning Dr. LeBon's writings, Mr. Campbell said:

I was a student of that author's works two years before his book appeared, and I believe that I have read every word that he has ever published on physical questions.¹

On the basis of this thorough knowledge, Dr. Campbell places an extremely low estimate upon LeBon's work.

I have not read all of LeBon's writings by any means, but very certainly the present book on "The Evolution of Forces" is of little or no account, except in one respect only. If one wished to diagnose the ills of contemporary French science, one would find in LeBon exaggerated symptoms of a malady (not of course affecting all French scientists) which has resulted from the tremendous scientific preeminence of the French during the early part of the nineteenth century. Let one consider the state of mind of a man who can express himself after the manner of the following quotations which are taken almost at random from LeBon's book:

¹The *Athenæum*, March 3, 1906.

This happy confidence in the great dogmas of modern science remained unaltered until the quite recent date when unforeseen discoveries condemn scientific thought to suffer doubts from which it imagined itself forever free.

There should, therefore, be no hesitation to examine closely the fundamental dogmas of science, for the sole reason that they are venerated and at first sight appear indestructible.

After I had proved that the dissociation of atoms was a universal phenomenon and that matter is an immense reservoir of energy hitherto unsuspected in spite of its colossal grandeur, etc.

Speaking of a certain matter, LeBon says:

As I expected, it was one of those classic errors repeated without verification to which repetition at length gives indisputable authority.

Speaking of another matter, he says:

All authors have regarded it as having a preponderating influence.

There is one idea which, according to my experience, seems to be dominant in the minds of young students, namely, that the physical science which they study in the technical school or college is in the text-book and was created by a literary effort of an author. Dr. LeBon, apparently, has never got beyond this childish idea. The word author, as applied to a scientist, is misleading. Our scientific men in the United States do not combine sufficiently the ability to write with the ability to search and search again, so that, although it is mildly ridiculous to call many of them authors, it would be a distinct affront to speak of them narrowly as such.

W. S. FRANKLIN

Contribution toward a Monograph of the Laboulbeniaceae. By ROLAND THAXTER. Part II. With 54 plates. Memoirs of the American Academy of Arts and Sciences, Vol. XII., No. VI. 4to, pp. 219-461. Cambridge, printed by Edward W. Wheeler. June, 1908.

Nineteen years ago Dr. Thaxter published his first paper on the Laboulbeniaceae,¹ and since that time has brought out many papers in which he has steadily added much to our knowledge of the species and genera and still

¹"On Some Species of North American Laboulbeniaceae," *Proc. Am. Acad. Arts and Sci.*, Vol. XXIV., February, 1890.

more of the structure and development of these curious entomogenous fungi. About twelve years ago he brought out "a stately quarto volume of two hundred and forty-two beautifully printed pages and twenty-six plates crowded with six hundred and seventy-two elegantly drawn figures," which the present writer reviewed in the *American Naturalist* (1897, p. 513). In this volume, which bore the same title as the one now before us, 28 genera and 158 species were recognized. And now in the second volume these numbers are increased to "more than fifty genera," and "about five hundred species and varieties." And we are told that since the completion of the plates "considerably more than one hundred additional new species have already accumulated," of which it is the author's expectation to publish figures and descriptions "with as little delay as possible."

The present publication adds to our knowledge of the structure of these plants in an instructive introductory chapter. In a brief and cautious discussion of their relationship Dr. Thaxter says:

They are more surely Ascomycetes than many forms included in this group, and the writer sees no sufficient reason why they should not be placed in the Pyrenomycetes, as a group coordinate with Perisporiales, Hypocreales, etc.

In the systematic portion of the work the genera are arranged under two groups (orders?) viz., (I.) *Laboulbeniineae*, in which the antheridia are composed of "specially differentiated cells or groups of cells," and (II.) the *Ceratomycetinae*, in which the antheridia are composed of "more or less undifferentiated cells of the appendages or of their branches." In the first three are two families (?) viz., (1) *Peyritschellaceae* (of 19 genera), with compound antheridia, and (2) *Laboulbeniaceae* (of 28 genera), with simple antheridia. The second order (?), which is composed of mostly aquatic plants, contains eight genera. The 44 plates are, if anything, better even than those in the previous volume, and enable one to get some idea of the structure of these very curious plants.

Dr. Thaxter asks his correspondents to communicate any additional material they may

have, and it may be well to repeat here the suggestions he made in his earlier contribution in regard to the collection and preparation of *Laboulbeniaceae* for study (pp. 248-249).

The collection of *Laboulbeniaceae* involves little more than the collection of a sufficient number of the proper hosts, although their presence on the latter is not always easy to ascertain in case of the smaller forms. In so far as concerns the collection of hosts my own experience . . . indicates that the most favorable localities in which to search for infested beetles is along the margins of small streams or of ponds. . . . Traps deposited in such situations, and made by raking together a heap of decaying grass, algae, etc., often yield large numbers of interesting specimens. Many forms may also be obtained by leaving bundles of hay or grass in cultivated ground for a few days and examining them over a sheet. Water beetles are in general best obtained by sweeping the margins of ponds or ditches with a dip-net. . . . Having obtained a number of hosts which are liable to be parasitized, it will be found that from about five to fifty per cent. will bear parasites. In order to obtain them for examination the host should be killed and impaled on a fine needle, care being taken that the surface of the insect remains perfectly clean and dry, and then examined over a dull white, and then over a black surface, with a hand lens magnifying about eight or ten diameters. . . . Every portion of the insect should be examined in different positions. . . .

Here is an opportunity for botanical collectors to exploit a new field near home, with the probability that new species or new hosts may be discovered. Any beetles on which these minute plants are found should be carefully packed, wet or dry, in clean cotton and sent to Dr. Thaxter, Cryptogamic Laboratory, Harvard University, Cambridge, Mass.

CHARLES E. BESSEY

THE UNIVERSITY OF NEBRASKA

The Loose Leaf System of Laboratory Notes.

By THEO. H. SCHEFFER, A.M. Philadelphia, P. Blakiston's Son & Company. 1908.

It fell to the lot of the present writer to review in *SCIENCE* of December 28, 1908, the first edition of this manual. The publishers have recently issued a "second edition, re-

vised." The revision comprises, as expressed by the author in its preface, "notes on three more types of animal life and is bound in a still more convenient form." Notwithstanding the closing statement of the author as to mode of binding, that of the former edition is continued without modification. On this point the reviewer had occasion to designate it as "the rather crude, shoe-string method." A more clumsy or inconvenient form of binding for such a manual could hardly be devised, and it is a pity the author's purpose of improvement might not have been realized.

Certain errors pointed out in the former review remain uncorrected in the present edition.

C. W. H.

Ergebnisse und Fortschritte der Zoologie—herausgegeben von Dr. J. W. SPENGLER, Professor der Zoologie in Giessen. Bd. I., Heft 1, 1907; Heft 2, 1908. Jena, Gustav Fischer.

The undertaking of Professor Spengel and a corps of collaborators to present the results and progress of zoological investigation in a series of annual volumes will meet the hearty approval of zoologists everywhere. The general plan is to issue a series of parts as they are ready, so as to make up a volume each year of between 600 and 700 pages. The parts before us at the present time contain the following contributions: (1) "Die Chromosomen als angenommene Vererbungsträger," by Dr. Valentin Häcker, 136 pages; (2) "Die verschiedenen Formen der Insectenmetamorphose, und ihre Bedeutung im Vergleich zur Metamorphose anderer Arthropoden," by Dr. Richard Heymons, 53 pages; (3) "Die Scyphomedusen," by Professor Otto Maaß, 50 pages; (4) "Die Amphineuren," by Dr. H. F. Nierstrasz, 68 pages; (5) "Die gegenwärtige Stand der Kenntnisse von den Copulationsorganen der Wirbeltiere, insbesondere der Amnioten," by Dr. Ulric Gerhard, 96 pages.

If the parts are a good promise of those to follow, it is obvious that the proposed series will have an exceedingly wide scope, so that the specialist in any particular field will not find his subject represented very often. But the object is rather to enable the student to

obtain authoritative information of the state of investigation in lines other than his own, and this object will certainly be admirably accomplished by such reviews with their full lists of references. The writer would raise the question whether it would not be better to classify the separate contributions so as to give each volume an individual character? The *pros* and *cons* on this question are perhaps sufficiently obvious, and it is also obvious from the list of contributions to the first two parts that the editor will not take the responsibility of giving invidious precedence to any subject.

The publication has a field of its own which is not covered by the *Zoologische Anzeiger*, *Zoologisches Centralblatt*, the *Concilium Bibliographicum*, the *Jahresberichte*, or by Merkel und Bonnet's *Ergebnisse der Anatomie und Entwicklungsgeschichte*. The separate contributions to the first two parts are admirably concise, sufficiently complete and critically excellent. One must admire the enterprise of our German colleagues, who find time in the midst of unremitting investigation to sum up and present to the world these necessary records of progress, which contribute to the progress itself by the mere process of organization. So long as German scientists are willing to perform such necessary functions in so admirable a way, we of a newer country and culture are relieved of such duties and should be properly grateful. American science is no longer an undiscovered bourn in Germany; on the whole, the contributions of American zoologists to the subjects treated receive adequate recognition.

FRANK R. LILLIE

UNIVERSITY OF CHICAGO

SIR WILLIAM RAMSAY ON TRANSFORMATION OF THE ELEMENTS

In the course of his presidential address before the Chemical Society, London, on March 25, Sir William Ramsay said, as reported in the *London Times*, that his subject was the hypothesis that the genuine difference between elements was due to their gain or loss of electrons. The question was whether, to take a concrete example, an atom of sodium by

losing or gaining electrons remained an atom of sodium, or whether the loss or gain of electrons did not cause it to change into some other element or elements. Having stated some theoretical arguments in favor of the possibility of transformation, he went on to describe some experiments bearing on the question. He first mentioned the transformation of radium emanation into helium, which had been amply established. He next referred to his experiments on the action of emanation on solution of copper sulphate and nitrate. Four experiments were made, and with each exactly similar duplicate experiments were tried in which no emanation was employed. A larger residue was obtained in each case from the emanation solutions than from the duplicates, and while the residues from the emanation solutions showed a faint trace of lithium, those from the duplicates failed to give spectroscopic evidence of the presence of that element. The fact of the experiments having been carried out in duplicate rendered inapplicable the criticism of Professor Hartley that accidental contamination with lithium was probable. As regards the alleged repetition of the experiments by Mme. Curie and Mlle. Gleditsch, who, using platinum vessels, obtained no greater residue and no trace of lithium, there were two possible replies—either the conditions were varied, or conceivably a trace of lithium from the glass vessel employed (which, however, had been tested for lithium with negative result) was dissolved in presence of emanation and copper but escaped solution in absence of copper or of emanation. A research on the action of emanation on solution of silver nitrate contained in a silica bulb yielded negative results, but he had stumbled across a case of apparent transformation while working in a totally different direction. On December 20, 1905, 270 grams of purified thorium nitrate were dissolved in about 300 c.c. of water, and the flask in which the solution was contained was repeatedly evacuated by a mercury pump until no gas could be pumped off. The stopcock attached to it was then closed, arrangements being made so that if any leakage occurred it would be detected. After the flask had stood for 188 days the gas

in it (5.750 c.c.) was pumped out and examined for helium with doubtful results. The flask was again closed, and on August 3, 1907, after 173 days, the gas in it was again examined. Again the presence of helium was questionable, but 1.08 c.c. of carbon dioxide was found. At the next examination, on March 30, 1908, there was distinct evidence of a helium spectrum, and the gas contained 1.209 c.c. of carbon dioxide. It was then thought possible that the carbon dioxide had been produced from the grease of the stopcock, and therefore a little mercury was introduced into the capillary tube leading to the stopcock so that the latter was protected from contact with the thorium solution. After 310 days the gas was again withdrawn. Instead of 3 c.c. or 4 c.c. no less than 180 c.c. were collected; it was almost pure nitrogen, but in all 0.623 c.c. of carbon dioxide was separated from it. These experiments, Sir William Ramsay said, rendered it at least probable that thorium engendered carbon dioxide, or, in other words, that carbon was one of its degradation products. Experiments further indicated that the action of radium emanation on thorium nitrate solutions was also attended with the formation of carbon dioxide, and the same was the case with an acid solution of zirconium nitrate. An experiment with lead chlorate proved blank, but with bismuth perchlorate the formation of carbon dioxide appeared certain. In conclusion Sir William Ramsay, after mentioning that every precaution which could be thought of was taken to exclude foreign gas, said that while these were the facts no one was better aware than he how insufficient was the proof, and that many other experiments must be made before it could be confidently asserted that certain elements, when exposed to "concentrated energy," underwent degradation into carbon.

POISONOUS EMANATIONS FROM FERRO-SILICON

LAST December five Russian immigrants, the only steerage passengers on the steamer *Ashton* from Antwerp to Grimsby, were found dead on the arrival of the vessel at the latter port. Owing to bad weather the steerage ac-

commodations were tightly closed, while beneath was a cargo of ferro-silicon. The deaths were at first supposed to be from cholera, or possibly from ptomain poisoning, but these causes were subsequently excluded. The only noticeable symptoms found on post-mortem examination were connected with the lungs, which were in all cases strongly congested with dark venous blood. Cultures from the stomachs and intestines showed in several instances the presence of numerous vibrios, which so closely simulated those of cholera that they were with great difficulty distinguished from these. Suspicion was finally turned to the ferro-silicon as the cause of death and a series of experiments instituted which revealed the fact that under the influence of moisture poisonous gases are given off. Mice placed in jars over ferro-silicon soon showed symptoms of dulness and somnolency. When the ferro-silicon was moist, death preceded by disturbances of movement ensued in a few hours. Guinea-pigs under similar conditions succumbed in ten hours. The only abnormal feature on post-mortem examination was congestion of the lungs, such as is usually seen in cases of suffocation. Experiments were further instituted to determine what gases were responsible for the fatal results. Acetylene and hydrogen silicid were excluded and arsin found only in traces. Small quantities of phosphin (phosphoretted hydrogen) were found to be present, and this seems to be the principal poisonous constituent of the emanation. While little is known of the toxicology of phosphin, it is stated to be so poisonous that 0.02 per cent. of it in the air is fatal to small animals in half an hour. As ferro-silicon is formed by heating iron ore, quartz, coke and lime in an electric furnace, and as phosphorus is usually present in at least two of these constituents, phosphide, which evolve phosphin on treatment with water, would be present in ferro-silicon.

This investigation has served to throw light on several deaths which have been recorded in the past three years, which were undoubtedly due to ferro-silicon. In August, 1907, four persons died on the steamer *Olaf*

Wijk, which was carrying ferro-silicon as part of its cargo. A short time before two children are recorded as dying on a Rhine steamer, having slept in a close cabin immediately over ferro-silicon, which composed a part of the cargo of the vessel. Four other cases of death on vessels carrying ferro-silicon are recorded, where the cause of death was not at the time suspected, but which are probably to be attributed to ferro-silicon.

As ferro-silicon is now used on a large scale in steel making, it is desirable that attention should be called to the fact that certain precautions should be taken in its transportation, especially that it shall be kept as dry as possible, and that it shall be well ventilated.

THE PHYSIOLOGICAL SIGNIFICANCE OF CREATIN AND CREATININ¹

Two fundamental observations have furnished the incentive to investigation and given the direction to hypotheses on the topic under discussion to-day. One of these was the discovery of *creatin* as a constant constituent of the muscular tissues of vertebrates; the other was the presence of *creatinin* in the urine of the higher animals. Creatin can be changed by the action of acids into creatinin, which in turn is supposed to form creatin in alkaline solutions. Since the chemist is able so readily to convert each of these compounds into the other in the laboratory, it was quite logical for the physiologist to assume some genetic relation between them in the living body. Creatin was looked upon as a product of protein metabolism in muscle, easily converted into its "anhydride" creatinin and thus eliminated in the urine. From this point of view two possible sources of urinary creatinin early suggested themselves, namely, an *exogenous* source in the muscle tissue (meat) consumed as food; and an *endogenous* origin,

¹Papers read at the joint session of Section K.—Physiology and Experimental Medicine—of the American Association for the Advancement of Science and the bacteriologists, biochemists and physiologists, Baltimore, December, 1908.

in the living muscles of the body itself. It was a further short step to associate muscular contraction with alterations in the creatin content of the contractile tissues; and to look for variations in creatinin output in relation to the muscular work done by the individual. In addition to this the creatin of the muscles has, because of its structural relationship, been discussed in the past as an important precursor of urea, on the assumption that the guanidin rest can be readily converted to urea in metabolism:

Ten years ago Dr. F. G. Hopkins wrote:

The variations in the urinary creatinin generally follow very closely those of urea, but there can be no doubt that its quantity depends largely on the amount of creatin taken with the food.

At that time the story was as simple as it was brief. The creatin of the muscle was in some way derived from the proteins of the body; the creatinin of the urine was referable to the creatin ingested or furnished by the muscles of the body. Feeding experiments with meat and its products seemed to bear out this view and analogies lent further support.

From the outset the study of these problems was hampered by the lack of a suitable process for the estimation of these compounds. The Neubauer method, in which creatinin is isolated as a double salt with zinc chloride, was practically the only one available. Older testimony and more recent critical investigations leave no doubt that this method is utterly unreliable as a quantitative procedure for the estimation of creatinin. All of the earlier work based upon it must therefore be attended with a probability of error which has necessitated a revision of the entire subject. Here, as in so many other instances in scientific research, a good experimental method has opened up entirely new fields of observation; and to Professor Folin is due the credit for a satisfactory quantitative procedure for estimating creatin and creatinin based on Jaffé's color test with picric acid and an alkali. It has

given the impetus to numerous investigations since its publication in 1904; in truth, this method, the simplicity of which makes it available in every clinic, has been responsible for a revolution in some of our ideas of metabolism. I propose to present some of these newer aspects of the physiology of creatin and creatinin, and to view them in the light of recent investigation; to inquire to what extent certain current hypotheses are justified. Bear in mind that a brief review within the limits of a symposium can neither be exhaustive nor do full justice to the newly accumulated mass of evidence; it is intended to be suggestive rather than critical—to propound problems rather than solve them.

Let us first consider the significance of creatin and creatinin in the muscle. The evidence now seems conclusive that creatinin is not present preformed in the muscular tissues (Grindley and Woods, '08; Mendel and Leavenworth). The fact that chemical manipulations of the extracts of muscle are quite likely to convert creatin into creatinin explains the constant occurrence of both of these compounds in commercial extracts of meat; and it warns against all conclusions regarding the physiological conversion of one compound into the other whenever appropriate conditions of analysis have not been rigorously maintained. When it is remembered that mere evaporation on a water-bath, under the acid reaction which arises post mortem, is sufficient to induce the conversion of creatin into creatinin, the liability of analytical error is emphasized. The difficulties are further increased by the fact that quantitative conversion of creatin into creatinin for analytical purposes is likewise attended with undeniable uncertainty (Folin, '06). These features are mentioned at the outset because they have served to complicate the experimental results to a degree where nothing short of experience seems to furnish adequate critique of the claims of investigators.

Creatin has been found in the muscles of all vertebrates which have been examined for it. From the phylogenetic point of view it is interesting, on the other hand, to note the absence of creatin from invertebrate muscle.

As we descend the scale it is still found in the lamprey, but missing in the arthropoda—the lobster and horseshoe crab, for example (Mellanby, '08; Lyman). This is only one of the chemical differences between vertebrate and invertebrate muscle and at once raises the question whether it is at all likely that creatin is functionally associated with contraction of muscle. Creatin apparently occurs in the non-striated variety of vertebrate muscle which is so frequently (and I believe without experimental justification) compared directly with the muscles of invertebrates (Saiki). Unfortunately, most of our information is still based upon the outcome of color tests rather than actual isolation experiments. Generally speaking the quantity of creatin seems to be larger in the muscles of warm-blooded animals, the hedgehog furnishing an unexplained exception in this series (Mellanby, '08).

Creatin is present in the embryonic tissues in mammals and in the developing chick, in which latter case it must be directly synthesized from the food-supply. Creatinin has not been found at any time (Mendel and Leavenworth; Mellanby, '08). In the chick the formation of creatin is apparently synchronous with, but independent of, the growth of the muscle. Mellanby has attempted to correlate the rapid increase in creatin during the later embryonic period with correspondingly rapid development of some organ, and naturally refers to the liver. He argues that since the cross-striated muscles of the invertebrates are identical with those of vertebrates—a contention which we are not inclined to admit as conclusive—and are creatin-free, muscle can not account for the phylogeny of creatin. Mellanby adds as a further biological speculation that since the "gland of the mid-gut" of invertebrates has no morphological or physiological connection with the liver of vertebrates, this newly introduced organ might account for the origin of creatin in vertebrate metabolism.

How constant is the creatin content of adult muscles; and is it altered during activity? In the light of the meager and conflicting data available to-day, a satisfactory answer can not be given to these questions. Yet they are of

fundamental importance for any adequate discussion of the rôle of creatin. Mellanby's convincing experiments on isolated muscles showed that muscular work leaves creatin unaffected, as does the survival of muscle. The stability of muscle creatin is the keynote of his contentions. On the other hand, Graham-Brown and Oathcart reported an increase in the so-called total creatinin in stimulated frogs' legs when the organs were isolated, and a decrease when the circulation remained intact. Weber and Howell and Duke have observed that the vigorously beating isolated heart gives more of these compounds to the fluid perfusing it, than does the quiescent organ. In this connection it is of interest that, according to Umano, the creatin of the muscle appears to be held in some non-diffusible form in the contractile tissue and is only released when the integrity of the muscle bundles is impaired. This observation may help to explain the unique property of muscle tissue to contain such conspicuous quantities of the compound.

We must bear in mind that all experiments such as those just reported are conducted under artificial conditions different from what pertains in normal muscular activity. The isolated or perfused muscles are working both without adequate repair of the contractile substance and under impoverished nutritive conditions. A disintegration of the tissues with possible liberation of creatin under such circumstances may be an incident in this *abnormal* situation rather than a customary expression of muscular contraction; just as we know that certain features of metabolism in starvation are the evidence of extraordinary katabolic changes rather than normal sequences. At any rate, we need to know more about the actual creatin content of muscle under a variety of both normal and unusual conditions, such as rest, activity, starvation and muscular disease, before the final word can be spoken.

The study of the metabolism of creatin and creatinin has lately received a new trend through the work of Gottlieb and his collaborators (Gottlieb, Stangassinger, Rothmann). An elaborate investigation of the behavior of

these compounds in autolysis led him to postulate that they can undergo a series of enzymatic transformations in the body, as follows: (1) Creatin can be formed in the autolysis of muscles and other organs. (2) Preformed or added creatin can be converted by enzymatic means into creatinin during autolysis. (3) In the progress of autolysis both of the compounds are destroyed by appropriate enzymes, creatase and creatinase. (4) The interaction of these processes affords a complicated curve for the creatin- and creatinin-content of autolyzing tissue extracts, since formation, conversion, and destruction may simultaneously go on. The behavior of creatin in the autolysis of different organs will vary according to the preponderance of one or the other of these different fermentative activities.

When we take into account the variations in the occurrence of these intracellular enzymes in the different tissues and note that the actual amount of creatin or creatinin found in an experiment at any moment represents the equilibrium point for a number of interdependent reactions the complexity of the situations becomes apparent. Truly a "bewildering array" of enzymatic processes, as Mellanby intimates in his severe critique of Gottlieb's work. Mellanby attributes the disappearance of creatin and creatinin to contaminating bacterial influences in these experiments; and he characterizes the conversion experiments as unconvincing because of the inappropriate analytical manipulations. Mellanby himself reports uniformly negative results on the behavior of creatin in autolysis. The repetition of these researches on the autolysis of tissues under more satisfactory conditions of control has, however, induced a number of investigators (van Hoogenhuyze and Verploegh, '08; Rothmann; Lefmann) to maintain the essential importance of endoenzymes in the metabolism of the compounds under discussion. Dakin has shown that arginase will not act upon creatin. The theory of the enzymatic transformation of creatin is comparable in many respects with accepted ideas regarding the metabolism of purins and other cellular products, and furnishes an

attractive working hypothesis; it must, however, be admitted with reserve, if at all, until it rests upon a more substantial basis than the uncertain evidence of a color reaction.

This brings us to the facts in regard to the elimination of creatin and creatinin. The normal urine of healthy individuals contains no creatin whatever, or at most only traces. Folin's well-known observations demonstrated that the output of creatinin in an individual is practically constant despite very wide ranges of (creatinin-free) diet. This fact, now abundantly verified in many laboratories, led to the conclusion that the excreted endogenous creatinin is the expression of the true tissue katabolism, as distinguished from the exogenous protein katabolism consisting of a series of rapid hydrolytic cleavages resulting in the elimination of protein-nitrogen as urea. As might be expected, the output varies with the bulk of the metabolic tissues of the body, averaging about 15 to 20 milligrams per kilogram of body weight. The attempt to connect the excreted creatinin with tissue creatin has brought to light an apparent independence of these compounds in metabolism. Ingestion of creatinin results in increased creatinin elimination; but when creatin is fed to man or animals the creatinin content of the urine is scarcely altered, if at all (Folin, '06; Klercker; van Hoogenhuyze and Verploegh; Lefmann). Observations by Lefmann also uphold this for creatin introduced parenterally. It would appear, then, that creatin, when fed, is not converted to any extent into creatinin in the body. Furthermore, in distinction from creatinin, the creatin of the diet reappears at best only in small part as such in the urine. In the noteworthy feeding experiments of Folin the nitrogen of the creatin which disappeared was in some cases assumed not to be recovered in any form in the urine, especially where the diet was deficient in protein. Folin has advanced the tentative hypothesis that creatin may be one of those special products which serve to maintain the nitrogen equilibrium in the living tissues, but which do not easily take part in the urea-forming process; hence the muscle is found rich in creatin. When the organism is daily supplied with an abun-

dance of protein it may be preparing as much creatin as is needed for the maintenance of its normal supply. Creatin given with the food is consequently not retained by the muscles to the same extent as when the food contains an insufficient supply of protein.

Widely quoted as these experiments have been, they are scarcely conclusive on this point. Van Hoogenhuyze and Verploegh ('08) have lately maintained that the variations in the daily nitrogen output are large enough to exceed the quantities which Folin failed to recover when creatin was fed with a low diet. All feeding experiments are further complicated by the difficulty of ascertaining whether creatin is to any considerable extent destroyed by bacteria in the alimentary tract and thus escapes absorption as such. At present there is no way of telling what became of the creatin-N in the feeding experiments on record.

If, as we have learned, ingested creatin fails to increase appreciably the output of creatinin in the urine, must we not admit that the creatinin of the urine has an origin quite independent of the creatin of the muscle? "It would be most remarkable," writes Klercker, "if the endogenous creatin of the muscle were changed into creatinin in the body, whereas ingested creatin is not transformed in this way." It is, however, no more remarkable than the fact that ingested cystin may be completely oxidized in patients who are at the same time excreting the cystin which arises in their intermediary protein metabolism.

The recent investigations with the Folin method have shown that neither increased nor decreased muscular activity uncomplicated by other factors has any effect upon the excretion of creatinin (van Hoogenhuyze and Verploegh, '05; Shaffer, '08). This fact of itself can not speak against the origin of creatinin from creatin so long as it is not known what part creatin may play in the contraction of muscles. Shaffer has calculated a "creatinin-coefficient," representing the milligrams of excreted creatinin-N per kilogram of body weight, in a large number of individuals. This "coefficient" is regularly found low in individuals with lowered muscular efficiency and shows a parallelism with the muscular development

and strength. He concludes that creatinin is not an index of the total endogenous protein katabolism, but is probably derived from, and an index of, some special process of the normal metabolism taking place largely, if not wholly, in the muscles. And upon the intensity of the process appears to depend the muscular efficiency of the individual. As a theory of metabolism this statement affords us little help; but as an expression of fact it elucidates a variety of interesting conditions. Thus the coefficient is found low in women, who as a rule are less developed muscularly than men; in infants with small bulk of muscular tissue; in the feeble aged; and in patients convalescent from wasting disease.

Creatin, not present in normal urines unless creatin is taken as food, is found in the urine during inanition and in certain pathological states. In starvation the creatinin output has been found to diminish gradually with the progress of the inanition. This is true likewise of another endogenous product, uric acid. The unique appearance of creatin under these circumstances must be borne in mind wherever this substance is found accompanying abnormal conditions attended by inadequate nutrition. In every such case it is reasonable to ascribe the source to the creatin of the muscles. Creatin may be excreted in acute fevers and various manifestations where there is a rapid loss of muscle proteins. Large outputs have been found in the urine of women during the first week post partum, when resolution of the uterus is taking place (Murlin; Shaffer). The fact that the creatinin elimination bears no appreciable relation to creatin in these conditions speaks further for the biological independence of the compounds.

There are numerous data already on record in attempts to connect the liver and other organs with the phases of metabolism which we are considering. It is almost too early to interpret these adequately because of the complexity of factors involved (Mellanby, '07; Spriggs, '07; van Hoogenhuyze and Verploegh, '08). In many instances, especially in the cases of hepatic disease, under-nutrition is an ever-present complication. Other cases, such as the muscular dystrophies with lowered cre-

atinin output, have a more immediate interest. Clinical investigators seem to forget that in these experiments of nature one rarely deals with simple conditions where a single organ, such as liver or muscle, is independently involved.

To attempt to formulate a theory of creatin and creatinin metabolism at this time would, in my judgment, be premature. It may, however, help us to crystallize the discussion by outlining some salient points of view. I think it will be agreed that the muscle plays a comparatively small part in the formation of creatinin. Let us assume for the moment that creatin represents a metabolism product originating in various organs, perhaps notably in the liver. It is transported about and especially deposited in the muscle in some non-diffusible combination. Most of it will be destroyed in ways that may be facilitated by enzymes. Here again it appears likely that the liver plays a prominent rôle. A part may be changed to creatinin, which may in turn be either destroyed or excreted. For this part of our hypothesis the evidence is most uncertain. Creatinin behaves as a waste product; it is decomposed with greater difficulty than is creatin, and it is eliminated more readily. But whether it represents a real end product, or like uric acid is an intermediary product, the output of which we associate with a balance between productive and destructive processes, can not yet be determined. At any rate, unchanged creatinin is promptly excreted and is nowhere to be found in detectable quantities in the organism. When the functional activities of the body are depressed or stimulated corresponding variations in creatin production and destruction may go on (van Hoogenhuyze and Verploegh, '08). So long as effective katabolic powers are maintained, the variations in creatinin output will be slight at most and in correspondence with the physiological state. Any excess of creatinin will represent only a fraction of the undestroyed increase in creatin. From this point of view the muscles would furnish creatin only as physiologically active organs and not as an incident of their contraction. The energy for contraction comes from quite different sources.

When, however, the tissues are drawn upon for supplies, as in hunger or cachexia, creatin is liberated by the disintegrating muscle; and owing to the lowered effectiveness of the katabolic organ, let us say the liver, the creatin now escapes destruction and is eliminated as such. In other words, in normal metabolism creatin is continually produced and destroyed, or converted to creatinin which is speedily eliminated. In starvation preformed creatin is liberated; and neglecting to experience the customary destruction, it escapes unchanged. Here creatin is a product both of metabolism and of tissue resolution.

It is an easy task to offer objections to the outline just presented. A primary source of difficulty lies in the failure of most investigators to demonstrate that creatin, introduced into the circulation, in any way affects the output of creatinin. I have already spoken of this fact. Perhaps we have not yet succeeded in imitating the conditions of equilibrium which pertain in normal metabolism. Mellanby has protested against the conventional interpretation and lays primary emphasis upon creatimin, which he regards as being continually formed in the liver from substances brought to it. In the developing muscle this is changed to creatin and stored as such until a saturation point is reached, whereupon creatinin is continuously excreted. Mellanby urges that from a chemical point of view it is easier to assume the preliminary production of a cyclic structure like creatinin and its subsequent conversion to creatin, than the reverse process. Creatin is neutral and innocuous, and not likely to be changed to the strongly basic creatinin. The argument is teleological and not convincing; and to the liver are ascribed functions for which there is little evidence under either theory.

More profitable than this hypothetical discussion will be a consideration of some of the investigations which are immediately demanded. At the outset we need to know more definitely about the possible distribution of creatin in the tissues and blood; and above all, whether the creatin content of the muscle is normally a constant, as some maintain, or subjected to variations incident to activity,

growth or atrophic changes. In view of the growing mass of data on the fate of ingested creatin and creatinin there is an unfortunate paucity of information regarding the changes which they experience after parenteral introduction into the body, where the uncertainties of change or loss in the alimentary tract are obviated and exact dosage becomes a possibility. The tendency to relegate important metabolic functions to the liver points to the desirability of studies on the fate of the nitrogenous katabolites in animals in which the hepatic functions have been excluded. In the only reference which I have found on this point, creatin was reported in noteworthy amounts in the urine of a dog after the Eck fistula operation and further extirpation of the liver (Salaskin and Zaleski).

The questions raised by the discussions regarding the intervention of enzymatic processes are timely and preeminently significant. Here, however, the limitations of the present colorimetric method are most likely to impede satisfactory progress and they invite the consideration of the analyst. The nature of the relation between inanition and excretion of creatin must be analyzed into its possibilities. Are we dealing with a general depression of katabolic organs in inanition? Or is the absence of metabolizable energy-yielding products in the tissues the sole factor? These questions are being investigated at present in our own laboratory. The behavior of the creatin bodies in the presence of microorganisms of the alimentary tract likewise deserves study, especially in view of the constant finding of methylguanidin among the products of bacterial action on creatin (Nawiasky), and of methylguanidin and dimethylguanidin in the urine (Achelis).

One can not conclude this topic without reference to the possible nitrogenous precursors of creatin and creatinin in the body. Speculation has been rife and claims have been numerous. That protein feeding does not *per se* increase the output in the urine has been conclusively demonstrated. Experiments with nucleic acid compounds (with thymus glands) which yield purin and pyrimidin derivatives structurally similar to creatin,

have had a negative outcome (Burian; Jaffé; Dorner; Lefmann).

The experience with methylguanidin and with glycoeyamin (guanidin acetic acid) is negative or uncertain at best (Jaffé; Dorner; Achelis). W. Koch's hypothesis relating creatinin to the metabolic change of methyl groups in the body and connecting it with the metabolism of the phosphatids (lecithin and cephalin) remains an interesting but unverified assumption. The guanidin derivate arginin stands structurally in close relation to creatin; while histidin, with its imidazole structure presents little more than analogy.

With neither of these compounds have experimental relations to creatin and creatinin been established. The nature of their synthesis still remains within the realms of surmise, inviting the organic chemist, as has so often been the case in biology, to supplement the efforts of the physiologist.

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION D—MECHANICAL SCIENCE AND
ENGINEERING

THE meetings of the section were held in the lecture rooms on the third floor of the chemical laboratory of the Johns Hopkins University. In the absence of President G. F. Swain, the vice-president of Section D, Professor Mansfield Merri- man, was chosen to preside over the meetings of the section.

Professor C. A. Waldo was elected a member of the council.

Professor C. M. Woodward was elected a member of the sectional committee.

Professor Mansfield Merriman was elected a member of the general committee.

Mr. J. F. Hayford was elected vice-president for the ensuing year.

The program consisted of eight papers read by their authors, five papers read by the secretary in the absence of the authors and three papers read by title in the absence of the authors.

The vice-presidential address which was to have been given by Professor O. H. Landreth on the subject "Governmental Control of Public Waters" was omitted on account of the unavoidable and unexpected absence of Professor Landreth. The address will be published in full in a later number of SCIENCE.

Mr. B. R. Green, of the Library of Congress, Washington, D. C., in speaking on the subject "Library Book Stacks without Daylight," said in substance that daylight is extremely variable, uncertain and expensive to secure in the construction of a library book stack. At best it is injurious to the books. At least it is almost useless. Stacks must be used much at night, requiring artificial illumination. The modern electric light solves the difficulty, and, at small expense, enables the stack to be built and enclosed anywhere and be perfectly illuminated at any and every desired point within it at any time of day or night. During the discussion the writer pointed out the great economy of space which can be effected where dependence is not placed upon daylight, and cited dimensions and other data from additions to the stack space recently made in the Library of Congress.

"The Testing of Transformer Steel" was presented by Mr. M. G. Lloyd, of the Bureau of Standards, Washington, D. C. In his paper he described a new apparatus for determining the constants of transformer steel, which apparatus is a modification of the Epstein apparatus, and presented tabulated and charted results obtained with the new apparatus from ordinary steels and from the special alloy steels now being used for transformer cores.

Mr. J. H. Hayford in demonstrating that "It is not Necessary to Place Geodetic Arcs in Various Latitudes" said, in effect, that the idea seems to prevail that, in order to determine the flattening of the earth from geodetic measurements it is necessary to make the measurements in various latitudes. The basis for this idea is that the flattening must be determined by measuring radii

of curvature of the spheroid which differ considerably from each other, and that arcs of the meridian in high latitudes, near the poles, have relatively long radii of curvature and those near the equator relatively short radii. But the attention should not be confined to arcs of the meridian. Since the introduction of the telegraphic method of determining longitudes, arcs of the parallel are as important as arcs of the meridian.

The flattening may be determined by measuring the difference of the radii of curvature of two arcs in any latitude, one an arc of the meridian and the other an arc of the parallel. The measurement of the latter determines the radius of curvature of the spheroid in the prime vertical plane, which, in all parts of the United States, is much longer than the radius of curvature in the meridian. The prime vertical radius is longer in latitude 49° than the meridian radius in latitude 67° . By utilizing measurements of both arcs of meridians and arcs of parallels made within the United States as great a difference of radii can be secured as from arcs of the meridian alone, scattered from latitude 20° in southern Florida to latitude 67° in northern Alaska, and three fourths as great a difference as can be secured from arcs of the meridian scattered from the equator to the poles.

These and other considerations indicate that progress is to be made in determining the flattening of the earth from geodetic measures, by securing large continuous areas of triangulation well supplied with astronomic observations, these areas to be in the most convenient localities, rather than by securing measurements of arcs of the meridian scattered through a large range in latitude.

Mr. J. Burkitt Webb, of Hoboken, N. J., discussed the subject of "House Warming." The following is an abstract of his remarks:

Direct and indirect heating, or heating by radiation and convection were compared and the former held most natural and preferable; the poisonous nature of the air of the ordinary hot-air furnace was exposed and compared with the wholesome effect of a fireplace, and hot water or steam heat discussed as a mean between the two.

The relative advantages of steam and hot water and the methods of installing these systems; the position, shape and color of radiators; the methods of generating and distributing the steam or hot water, and the method of regulation were discussed.

Professor C. N. Ricker, of Urbana, Ill., in a paper entitled "A Study of Plain Metal Base and

Bearing Plates," which was illustrated by twenty-five or thirty lantern slides, presented a summary of a bulletin soon to be issued by the Engineering Experiment Station of the University of Illinois.

The author deduced the proper theory of resistance of base plates, formulas for the safe thickness of plates of rectangular and tapered cross-sections of cast iron, and recommended the substitution and use of the straight line formula in place of the theoretical formula of very tedious application, the construction and use of a series of graphical tables for rapidly and accurately determining the dimensions and thickness of base plates employed in practical construction.

Professor A. H. Blanchard, Providence, R. I., who is assistant engineer for the State Board of Public Roads of Rhode Island, presented "An Analysis of Highway Traffic in Rhode Island."

The conclusions drawn by the writer for the roads examined are:

1. The amount of motor-car traffic which will cause disintegration is much less than is generally supposed.
2. In the case of two roads subjected to practically the same amount of motor-car traffic, the rate of disintegration will depend upon the location of the road, other conditions being equal.
3. The rate of disintegration of an ordinary macadam surface will vary almost directly as the percentage of motor-car traffic.
4. The popular belief that trap rock is the ideal road material for the surface of all macadam roads independent of the nature of the traffic to which they are subjected is a fallacy. In the case of roads subjected to horse-drawn vehicle traffic consisting of pleasure and light commercial traffic, or subjected to motor-car traffic, either exclusively or in combination with light horse-drawn vehicle traffic, the trap rock surface is exceedingly expensive to maintain. This is due to the fact that very little dust is furnished by abrasion on account of the hardness of the broken stone and hence, the binder being absent, the surface ravel under horse-drawn vehicle traffic or is disintegrated by motor-car traffic.
5. Bituminous macadam roads require a sealed surface when the highway traffic consists of a combination of heavy motor-car traffic and heavy horse-drawn vehicle traffic, while the sealed surface is not a requisite when the road is subjected to only heavy motor-car traffic. The sealed surface is considered necessary for the first class as insurance against the disintegration of the surface due to the liability of the loosening of the exposed stone by blows from the hoofs of horses

and the rapid enlargement of any break in the surface by motor-car traffic.

"Recent Progress in Aeronautics," by Major G. A. Squier, U.S.A., has already appeared in *SCIENCE* (February 19, 1909). The lecture was very completely illustrated with lantern slides and set forth the present state of the art in a pleasing and impressive manner.

In this connection, it should be noted that the association has decided to foster this growing branch of applied science. The council will refer all papers on engineering and aeronautics to Section D, whose officers will cooperate with their authors for adequate presentation and publication.

In the paper on "State Engineering Experiment Stations," by Professor G. W. Bissell, East Lansing, Mich., the writer reviewed and compared some of the provisions of the Hale and the McKinley experiment station bills, of which the latter is now before Congress and presented the principal arguments for such a measure.

The following papers were read by the secretary in the absence of the authors:

New Methods of Back-water Computations: Professor B. F. Groat, Minneapolis, Minn.

Variation of Pressure on the Side of a Track Spike: Professor H. S. Jacoby, Ithaca, N. Y.

Note on Specially Designed Corliss Engine for Experimental Work: Professor A. M. Greene, Jr., Troy, N. Y.

The Specific Speed of Hydraulic Turbines: Professor L. P. Moody, Troy, N. Y.

On the "Degree" of Railroad Curves: Professor W. G. Raymond, Iowa City, Iowa.

The following papers were read by title:

A Problem for State Engineering Colleges: Professor A. E. Haynes, Minneapolis, Minn.

Temperature Stresses in Reinforced Concrete Chimneys: Professor E. R. Maurer, Madison, Wis.

A New Type of Reinforced Building Construction: Professor J. J. Flatner, Minneapolis, Minn.

All papers were interesting and valuable and evidenced care in their preparation. The program should have been published in *SCIENCE* in advance. The secretary will see that this is done for the next meeting.

G. W. BISSELL,
Secretary

SOCIETIES AND ACADEMIES

THE NEBRASKA ACADEMY OF SCIENCES

The nineteenth annual meeting of the Nebraska Academy of Sciences was held in Lincoln, Feb-

ruary 12 and 13. A larger number than usual of members out in the state were present. President A. A. Tyler delivered the president's address, on "Evidences of Evolution from the Development of Leaves."

The following papers were read before the academy:

"The Brown Chert of the Republican Valley," by E. E. Blackman.

"The Manufacture of Hog Cholera Vaccine," by A. T. Peters.

"The Season of 1908 in the Sioux County Bone Beds" (illustrated), by E. H. Barbour.

"Geometry as Pure Mathematics," by E. W. Davis.

"Paint and the Protection of Lumber," by J. Mortenson.

"Modeling Plant Structures in Paraffin," by R. J. Pool.

"A Preliminary Study in the Ethnobotany of Nebraska," by M. R. Gilmore.

"Notes on Western Indian Language," by A. E. Sheldon.

"The Scientific and Practical Value of Making Nebraska a Tuberculosis-free State," by H. W. Orr.

"A Plan for Completing the State Flora," by C. E. Bessey.

"Some Features of the Flora of Grand Island, Nebraska," by C. J. Elmore.

"The Problem of Defective Sight," by H. B. Duncanson.

"Comparison of Parasitic Fauna in Atlantic and Pacific Salmon," by H. B. Ward.

"Are Species Realities or Concepts Only?" by J. H. Powers.

"Legislative Restrictions to Animal Experimentation," by A. E. Guenther.

"The Importance of a Sanitary Milk Supply," by H. H. Waite.

"Is the Number of Chromosomes a Test in the Alternation of Generations in Plants?" by R. J. Pool.

"Notes on the Missouri Valley Loess," by S. W. Stookey.

"Measurements of Evaporation in Nebraska," by G. A. Loveland.

The session on Saturday afternoon was given over to a symposium on the "Economic Resources of Nebraska" with the following subjects and leaders:

"Trees"—Professor F. J. Phillips.

"Birds"—Professor R. H. Wolcott.

"Insects"—Professor L. Brunner.

"Forage and Fruits"—Professor C. E. Bessey.

"Minerals"—Professor G. E. Condra.

"Fish"—Professor H. B. Ward.

The academy accepted the invitation of the Nebraska Chapter of the Sigma Xi to hear the address of Professor A. G. Webster, of Clark University, on "The Creed of a Scientist," and adjourned its regular meeting on Friday evening in order to join with the botanical seminar in a Darwin anniversary meeting with the following program:

"Pre-Darwinian Evolution," by Mr. Pool.

"The Life of Darwin," by Dr. Walker.

"Darwin as a Zoologist," by Professor Ward.

"Darwin and the Geological Record," by Professor Barbour.

"Darwin's Contributions to Botany," by Professor Bessey.

"Darwin's Contributions to Plant Physiology," by Professor Wilcox.

The following were elected officers of the academy for the coming year:

President—Professor G. E. Condra, Lincoln.

Vice-president—Professor A. T. Bell, University Place.

Secretary—Professor F. D. Barker, Lincoln.

Treasurer—Professor R. J. Pool, Lincoln.

F. D. BARKER,
Secretary

THE ACADEMY OF SCIENCE OF ST. LOUIS

ON Monday evening, February 15, 1909, the regular meeting of the St. Louis Academy of Science was held at the Academy Building, 3817 Olive Street. The following program had been arranged by the committee to commemorate the centenary of the birth of Charles Darwin (February 12, 1809):

"Darwin as a Naturalist," Professor S. M. Coulter.

"Darwin's Influence upon Geology," Professor W. E. McCourt.

"The Natural Selection Theory and its Later-Day Critics," Professor J. F. Abbott.

"Some Aspects of Darwin's Influence upon Modern Thought," Professor A. O. Lovejoy. (Read by Dr. Joseph Grindon.)

At the conclusion of the special program, Professor Nipher presented to the academy some changes in the manner of his experiments, and some of the additional results that he has obtained in his studies of "Momentum Effects in Electric Discharge"—reports of which have from time to time appeared in *SCIENCE*.

He reported that he had modified the arrangement of the wire forming the angle, in his study

of momentum effects in electrical discharge. The angle is now formed as follows: A vertical wire leads downward to the plate-holder. Its lower end terminates in a pin, the head of which is soldered to the end of the wire, and the point of the pin is just above the cover of the plate-holder. Its distance from the cover can be varied by vertical adjustment. The horizontal wire forming one side of the angle has one end soldered to the vertical wire, thus making a right angle. The distance from this junction to the pin may be varied. Satisfactory operation is obtained when the junction is midway between the head and the point of the pin. In this way a right angle is formed with a discharge point below the vertical wire, and in line with it. Such angle-wires may be coupled with each other by joining either their horizontal or their vertical wires. The results are the same as those announced heretofore.¹ But the results are more easily obtained with this arrangement than with the one previously described.

Professor Nipher also finds that the shadow pictures obtained depend upon the material of the plate-holder. With a cover of paper or thin hard rubber, the presence of electrons is shown by branching discharge lines from the images on the film. Refraction effects are also clearly shown. When the cover is of glass or mica, with black paper, the images are like those formed by X-rays, and no refraction is shown.² By using a machine of large capacity and by arming a metal plate with many points directed toward a sheet of glass, shadow pictures of larger objects may be obtained.

W. E. McCourt,
Recording Secretary

THE TORREY BOTANICAL CLUB

The first meeting of the club for 1909 was held at the American Museum of Natural History on January 12, President Rusby in the chair.

This being the annual meeting, reports were presented by the treasurer, editor, chairman of the field committee and secretary. These were read, accepted and placed on file.

The following officers were elected for the year 1909:

President—Henry Hurd Rusby.

Vice-presidents—Edward Sandford Burgess and John Hendley Barnhart.

Secretary—Percy Wilson.

¹ SCIENCE, July 14, 1908, and December 4, 1908.

² SCIENCE, February 5, 1909.

Treasurer—William Mansfield.

Editor—Marshall Avery Howe.

Associate Editors—John Hendley Barnhart, Jean Broadhurst, Philip Dowell, Alexander W. Evans, Tracy Elliot Hazen, William Alphonso Murrill, Charles Louis Pollard and Herbert Maule Richards.

The meeting of the club was held at the Museum of the New York Botanical Garden on January 28, President Rusby in the chair.

The scientific program consisted of two papers, of which the following abstracts were prepared by the authors:

Studies in the Embryology of the Mistletoe, Dendropemon: Miss MARY M. BRACKETT.

This study was made from two species of Loranthaceae—*Dendropemon caribaeus*, gathered by Professor F. E. Lloyd from lime-trees in Dominica, and *Dendropemon parvifolius* collected by the writer from the bitter-broom, *Baccharis*, at Cinchona, in the Blue Mountains of Jamaica.

The flowers of *Dendropemon* are perfect, regular and symmetrical. The buds form in clusters of three in the axils of the leaves, and are protected by bracts. The corolla consists of six petals, which, in *D. parvifolius*, are of a reddish color on the outside, and a delicate pink within. There are six stamens borne upon an inferior ovary, the three fertile stamens alternating with three sterile stamens. The flower has one style and one stigma. At the top of the ovary is the cup-shaped calyculus.

At the time that the corolla and stamens appear as rounded knobs, two carpellary leaves meet over a central placenta, forming a cavity. The carpellary and placental tissues gradually unite, filling the cavity. Growth in the length of the pistil begins to be rapid, and the stamens develop. During this time cell-division is going on in the region of the nucellus. There is, however, nothing to mark the development of an ovule as a distinct organ, nor is there any indication of integument. In the center of the ovary the cells increase in number and size and contain large nuclei. They elongate parallel to the main axis, become irregular, and constitute the archesporial tissue. Their growth is accompanied by periclinal division in the adjacent cells. Several large archeaporial cells form megaspores; the neighboring cells become disorganized and gradually disintegrate. Apparently only one of the megaspores becomes an embryo-sac.

The embryo-sac was not made out in these species; but a long slit was observed reaching from the center of the ovary into the tissues of the style, which, it seemed, had been occupied by the embryo-sac. Of this Hofmeister says ("Neue Beiträge zur Kenntniss der Embryobildung der Phanerogamen," 539. 1859): "The growth in length of the embryo-sac is not ended with its formation. The sac makes its way through entangled cells of the closed style to a quarter of its length upwards."

Young stages of the proembryo were observed composed of four, and then of six cells in two parallel rows, with the long suspensor, of three greatly elongated cells, reaching into the tissues of the style for nearly half its length.

The embryo occupies a vertical position in the center of the berry, and from its position in the surrounding tissue, suggests all the characters of an orthotropous ovule. As the embryo develops, it is surrounded with endosperm. A change in the nature of the tissue below the embryo suggests a series of conducting cells between the embryo and the starch-filled cells in the lower part of the ovary. The cotyledons become green, and the suspensor gradually disappears, except for a few capping cells at the anterior end of the embryo, which now occupies the ovarian cavity for almost its entire length.

The points of particular interest are: the rapid disintegration of the cells of the gynecium before and after fixation; the lack of an ovule as a distinct organ; the lack of integument; and the green color of the embryo as it lies in the berry.

Botanical Observations in Iceland and Spitzbergen. Miss JULIA T. EMERSON.

In July, 1908, the writer was so fortunate as to take a three-weeks' trip, touching at the following places: Kirkwall, in the Orkney Islands; Thorshavn, the chief town of the Faroes; the city of Reykjavik and village of Akreyri, in Iceland; Advent Bay and Bell Sound, in the Island of Spitzbergen; and then south to the North Cape of Norway and many places of interest on that coast.

Although all the points visited were on the coast or within reach of salt water, the flora changed according to the latitude, just as it does when one climbs a mountain, and as we went north we left behind the summer or spring vegetation which we found in Kirkwall, passed a treeless growth in Iceland, and at Spitzbergen came

to an alpine flora with representatives found in the United States only on mountain summits or in the high Rockies. For instance, at Thorshavn buttercups, marigolds, forget-me-nots, daisies and other spring flowers were in bloom, and there were potatoes and gooseberries in the gardens. Our first sight of Iceland had been of great snow-fields, and we were astonished, therefore, to find any familiar plants on land. In the town were some of the plants mentioned above and two little specimens of trees, a sycamore maple and a mountain ash, very stunted, and the vegetables would not have grown without protection of the houses and good soil; on the great stony stretches which surround Reykjavik a little pink thyme, *Statice maritima*, *Silene maritima* and *S. acaulis*, *Polygonum viviparum*, *Alchemilla alpina*, several species of *Galium* and *Tofieldia palustris* were more or less abundant, and at Akreyri there was quite a luxuriant vegetation near a little waterfall outside of the settlement; pretty *Dryas octopetala*, *Eriophorum angustifolium* and *E. vaginatum*, *Parnassia palustris*, *Viola tricolor*, *Pinguicula vulgaris* and some of our ordinary weeds, also a number of mosses, especially *Grimmias*. At Spitzbergen the stones, where not covered by snow, were gay with the Iceland poppy, *Saxifraga oppositifolia*, pink or white and with a delicate odor, beautiful *Pedicularis lanata*, the pink of the flowers showing through a veil of gray hairs, *Potentilla emarginata* and *Cassiope tetragona*, making a sort of turf or bog close to the melting snow. Here we had twenty-four hours of sunshine, and the scenery was of strong contrasts, wet black or gray rocks, dazzling glaciers and dancing blue waters, where numberless birds fearlessly rested or floated about.

The contrast between these arctic conditions and the rich growth of grass, sweet yellow violets, pink campions and geraniums, etc., which we found growing in the flank of the North Cape of Norway, was very marked, but on the flat top of the cape there was only a scanty number of hardy stone-crops and other low things which could find protection between the stones from the fierce winds. The first trees seen on the southward part of the journey were birches, and they were at Lyngenfjord, still north of the arctic circle. In climbing the mountain at Digermullen we noticed the following plants, *Calluna vulgaris*, whose common name of "lyng" is said to have suggested the name of the fjord, *Cornus suecica*, violets, *Trientalis europæa*, *Vaccinium* and *Andromeda polifolia*.

Two days spent at Merok and Gudvangen showed their stupendous cliffs and beautiful fjords were a fitting climax to an inspiring and wonderful trip.

Dr. Merrill showed a photograph of a new and interesting mycad collected by Dr. MacDougal and Dr. Tomellin in Tomellin Cañon, Mexico, in 1906. The plant was sent to the New York Botanical Garden and installed in the propagating houses, where it remained for two years before showing any signs of growth. This appears to be a new species of *Myrica*.

Dr. Merrill exhibited a number of tropical fruits obtained on his recent trip to Jamaica.

The club met at the American Museum of Natural History on February 9, at 8:15 P.M., and was called to order by President Rusby.

The announced paper of the evening on "The Rubber Forests of Mexico" was then presented by Dr. H. H. Rusby. The lecture was illustrated by lantern slides made from photographs, many of which were obtained by the speaker while in the field. This paper has been printed in full in the January number of the *Journal of the New York Botanical Garden*, and an abstract accompanied by illustrations will appear at an early date in *Torreya*.

PERCY WILSON,
Secretary

THE AMERICAN CHEMICAL SOCIETY NORTHEASTERN SECTION

The ninetyeth regular meeting of the section was held at the Twentieth Century Club, Boston, on February 19. Dr. Arthur L. Day, director of the Carnegie Geophysical Laboratory, of Washington, D. C., addressed the section on "Some Recent Work in Geophysics." After pointing out the necessity of applying the principles of physical chemistry to the solution of many geological problems, the speaker described the electrical furnaces used in his laboratory for maintaining temperatures of about 1,500° C. He stated that the transition points for a number of one-component and two-component systems of minerals had been determined at this high temperature and that work was now in progress on a three-component system.

Professor Henry P. Talbot, of the Massachusetts Institute of Technology, presented a paper upon "Present Conceptions of the Action of the Common Indicators used in Acidimetry, and Some of

their Applications." The recent advances in the knowledge of the reactions which indicators themselves undergo in changing from acid to alkaline solutions was fully reviewed and the advantages to be derived by the proper choice of indicators was clearly illustrated by experiments.

KENNETH L. MARK,
Secretary

THE BIOLOGICAL SOCIETY OF WASHINGTON

The 454th meeting was held February 6, 1909, with President Palmer in the chair.

Dr. M. W. Lyon, Jr., exhibited skins and skulls of the oriental genus *Gymnura* and of the American opossum, *Didelphis*, and pointed out the close general superficial resemblances in external and cranial characteristics of these two groups of mammals from such widely separated portions of the world and members of different superorders, the Monodelphia and the Didelphia.

The chair noted the capture near Washington, on September 1, 1908, of a specimen of the little black rail, by Mr. H. M. Darling, on the eastern branch of the Potomac. For the locality this is the third actual specimen and fourth record of this the smallest of the game birds, the first record for the District of Columbia being in 1861. Though its range is from Massachusetts to the West Indies and Guatemala, the bird is seldom seen.

Dr. O. F. Cook, in a brief statement on "Mitapsis and Amitapsis," called attention to the possible importance of the recent investigations of Dr. Reginald R. Gates, of Chicago University, in the cytology of *Oenothera*. The suggestion was made that the lack of any evidence of fusion of chromatin threads at synapsis may be of more significance than the subsequent differences in the number or distribution of the chromosomes. The name *amitapsis* was proposed for the newly discovered condition in which no fusion of chromatin takes place, to contrast with *mitapsis*, the name given by Cook and Swingle to the process of chromatin fusion, considered as the final stage of the process of conjugation. Mitapsis has no necessary connection with synapsis, which is the name of the closely coiled condition of the chromatin skein. Gates finds synapsis in *Oenothera*, but no indication of mitapsis; the extremely delicate threads visible before synapsis are simple. A longitudinal splitting begins after synapsis, but is not carried out, and the new chromosomes are formed in a single chain.

If amitapsis should prove to be associated with self-fertilization it would help to explain why self-fertilized plants produce highly uniform progeny, as in vegetative propagation, whereas the progeny of normally cross-fertilized plants have notable individual diversity. Germ-cells arising through amitapsis could be viewed as vegetative products, rather than as fully sexual products of conjugation. It is easy to understand that the union of amitaptic germ-cells might merely reproduce the parental characters. Thus amitapsis may account for the uniformity of self-fertilized types, as well as for their liability to mutative derangements of characters.

The regular program consisted of the following communications:

The Blue Foxes of the Pribilof Islands: JAMES JUDGE.

The blue foxes of the Pribilof Islands are presumed to have come from the mainland of Alaska on the ice with which Bering Sea is filled during winter. The caves and subterranean passages left by the volcanic upheaval furnish the foxes with homes.

In summer the bird life furnishes an abundance of the choicest fox food. When the birds depart in the fall fox food consists of drift from the beach and the bodies of seals or sea lions which have either been killed, or died the preceding summer. This was ample until 1890, when the lessened seal and sea lion catches reduced the winter food supply and many of the animals died of starvation. The dead were eaten by the survivors, and the death rate in consequence was not noticed.

Since 1896 all seal meat not used by the natives on St. George Island has been salted and the following winter freshened and fed to the foxes. The seal meat, being insufficient in quantity, has been supplemented by dried or salt fish.

Coincident with the regular feeding begun in 1897, the old methods of trapping were abandoned. These consisted of death traps, so called, and steel traps, and a method of taking foxes from their warrens. The method of trapping now in vogue consists of capturing the animals in a large cage, in which the food intended for them is placed. Upon capture, the animals are subjected to a rigid examination and all undesirable ones are killed forthwith. Males left for breeding purposes must weigh at least 10 pounds and females at least 7½ pounds, and be either young or in the prime of life. In taking the live weights a strap

is looped around the tail and the beast suspended from a spring balance attached to the ceiling of the building. The age is determined by an examination of the teeth. This is done by inserting a soft gag in the mouth and inspecting the teeth at close range. Those dismissed as breeders are branded by cutting a ring in the fur of the tail, males being branded near the end, females near the base. The men handling the foxes use heavy leather mittens.

On post-mortem examination of the animals killed in trapping the stomachs are found to carry in addition to the bait taken in the trap, grass, feathers, wild parsnip, fish bones, bird or seal bones, dirt or sand, and occasionally tunicates, sea eggs and fox fur. The intestines vary between six and ten feet in length, and were found to carry grass, feathers, wild parsnip, dirt, gravel, bones and sometimes tunicates and fox fur.

The bulk of males weighed between 8½ and 13½ pounds. That of females between 6 and 11½ pounds. Male skins when ready for market measure on an average 30 inches in length, 11 in breadth; the females are about one inch shorter and an inch narrower. The tails of both sexes are about the same length, viz., 15 inches. As a rule the fur of the female is inferior to that of the male, and among the males the best fur is found on the two- and three-year olds.

The breeding season is confined to March and the first half of April, and the young are born in litters of from five to twelve, in May and early June. Birth is given on the surface of the ground, but shortly afterwards the mother transfers the young to some place under ground, from which they do not emerge until several weeks old. While the birth rate is large, the infant mortality is very great, as only about two per female, on an average, reach maturity. They are born blind and weigh about 2½ ounces each. The eyes open on the fifteenth day, by which time the head and the tail take on a fox-like appearance. The teeth come through at or shortly after this time.

Occasionally one white fox is found in a litter of blue. Since 1897 a continuous effort has been made to exterminate white foxes, and results indicate that in time this will be accomplished, or at least that the white strain will be reduced to a minimum.

Evidence of diseases is scanty. Two cases of tuberculosis, one of uremic poisoning and thirteen cases of mange have been discovered. From the evidence at hand the males seem better able to

require adverse climatic or other conditions than the females.

It is generally thought the animals pair for breeding purposes, but there is only one authentic case of paired foxes jointly engaged in feeding and guarding the same litter of young. The different methods of branding have shown that foxes often come together in the spring are of the same sex. There have been six cases of promiscuous intercourse witnessed.

It is customary on St. George Island to have the polar foxes bred for breeding purposes annually. After the breeding quota is secured all unbranded animals falling into the trap are killed and their skins skinned. The annual yield of skins varies between 400 and 500.

On St. George Island, where artificial feeding was maintained, while a sufficient nucleus remained, the fox is almost extinct.

The Law of Recombination in Second Generation Mendelism. V. J. SPILLMAN.

It was pointed out that Mendel discovered three important laws: namely, the law of dominance, the law of separation and the law of recombination in the second generation.

The first two laws have been adequately recognized by most breeders, but the third law, which is the most important from the standpoint of breeding practice, has not been sufficiently emphasized. The law of recombination may be stated thus: In the second generation of a hybrid there tends to appear every possible combination of the original parent characters, the proportion of the population constituted by each type being $\frac{1}{2^m}$, in which m is the number of characters with reference to which the type is heterozygote and n the total number of characters involved in the cross.

It was pointed out that in practice the application of this law is limited:

1. The number of individuals in the second generation, which must be numerous enough to permit the types to occur under the operation of the law of chance.

2. The hybrid must be fertile.

3. The presence of cryptomeric factors may give unexpected results.

4. Non-Mendelian characters would be independent of this law.

5. In some crosses, such as produced Burbank's Rutgers berry, irregularities in mitosis might counteract the application of the law.

The recent work of Professors Price and Drink-

ard on tomato hybrids was given as an illustration of the recombinations of original parent characters, each of the eight possible types being shown. Illustrations were given of polled Hereford cattle produced by crosses between horned Herefords and polled Durham cattle. The application of the law of recombination at the Washington State Experiment Station has resulted in the production of a winter club wheat which is now rapidly replacing the spring clubs of that section. These wheats yield considerably more than the common wheats of the section and are worth more for flour-making purposes.

The Lewis and Clark Cavern National Monument of Montana: V. K. CHESNUT.

The speaker exhibited lantern slides illustrating the features of great geologic and historic interest. The cavern which is remarkable on account of the great diversity of form, and the snow-white beauty of its drip rock, especially the helictitic forms, is a steep comparatively unexplored abyss in an isolated earth-block of Madison limestone very closely bounded on two sides by faulting planes of profound depth separating it from the Belt formation and the Three Forks shale. Including the various halls, grottoes and chambers already discovered it is about a mile in length, the largest single room being about 125 feet in diameter with supporting columns one to three feet thick running up to twenty feet in height. No excavation has been made for vertebrate fossils. The limestone itself is made up largely of blastoid stems.

Of the existing living forms the only specimen taken of unusual importance was a single phalangid spider, which has been credited recently by Professor Nathan Banks as the type of a new genus, *Cryptobunus*. The cavern, being 1,600 feet above the Jefferson River at Limespur, overlooks 75 miles or more of the Lewis and Clark route along the Jefferson and Gallatin rivers and hence it seemed appropriate that the cavern should be conserved forever a monument to the memory of these intrepid explorers. The proclamation creating it a national monument was made under the act of June 8, 1906, entitled "An Act for the Preservation of American Antiquities" and was signed by President Roosevelt on May 11, 1908.

M. C. MARSH,
Recording Secretary

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

THE 430th regular meeting was held March 2, 1909. A preliminary presentation and explana-

tion was made by Mr. C. H. Robinson of a number of pieces of pottery, principally from Alamakee County, Iowa. Afterward the president of the society introduced Mr. Charles F. Warren, of the Bureau of Labor, who delivered a lecture of popular character on "Mexico, Its People and Customs," illustrated by colored slides. In the course of this lecture Mr. Warren touched upon the cathedrals, public buildings, gardens, markets and characteristic customs in Mexico, Cuernavaca, Puebla, Guadalajara, Guanajuato, Oajaca and other places, gave some fine views of the ruins of Mitla, and some superb examples of Mexican scenery. Finally a word was added regarding the passing of the old Mexican life and the coming of the new under President Diaz.

THE 431st regular meeting of the society, March 16, 1909, was devoted to an address by Professor William H. Holmes, chief of the Bureau of American Ethnology, on "Outlines of South American Anthropology." Professor Holmes had just returned from the Pan-American scientific congress at Santiago, Chile, which he attended as special representative of the Smithsonian Institution.

He introduced his remarks by a brief sketch of the congress itself, and illustrated the journey by numerous water-color drawings. An outline of the geological development of the South American continent and the evidence of the presence of man during the Tertiary and Quaternary times were given. The tribes of the great Andean highland and their remarkable culture were described, and contrasted with the peoples and cultures of the lowlands. The wonderful progress made by the Incas, Aymaras and Chimus was illustrated by a large number of lantern slides.

Mr. W. E. Safford, of the Bureau of Agriculture, added some particulars gathered during his own sojourn in South America.

JOHN R. SWANTON,
Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 662d meeting was held on March 13, 1909, Vice-president Wead in the chair.

The following paper was read by invitation:

Balloon Voyages and the Use of Air Currents:
Mr. H. H. CLAYTON, Meteorologist of the Blue Hill Observatory.

The balloon was invented about one hundred and twenty-five years ago, and at first was of scientific interest only, being early employed by the English for meteorological observations. The

Germans were the next to make use of it for similar investigations.

The use of sounding balloons equipped with self-recording instruments, the methods and the results obtained with them over land and ocean areas in different regions of the globe, were discussed at some length. The results show that in the upper regions in temperate zones the trend of the air currents is easterly, while in the equatorial regions they are to the westward. In all the regions of the globe so far investigated inversion of temperature takes place at an altitude of nine miles or so; this occurs at all times of the night as well as the day, and the inversion is found to be somewhat more marked in the equatorial regions than elsewhere.

An interesting account was given of the voyage of the successful balloon in the Gordon Bennett international balloon race from St. Louis in 1904, in which the speaker was one of the invited participants. It was pointed out how the knowledge of the circulation of the upper layers of the air was utilized in making this balloon voyage of forty hours' duration to the Atlantic coast. A number of lantern slides were exhibited illustrating this voyage, and two subsequent ones which the speaker had made. It was the speaker's belief that the knowledge of air currents is destined to play an important part in the ballooning of the future.

R. L. STARR,
Secretary

THE ELISHA MITCHELL SCIENTIFIC SOCIETY OF THE UNIVERSITY OF NORTH CAROLINA

THE 181st meeting of the Elisha Mitchell Scientific Society was held in the main lecture hall of Chemistry Hall, Tuesday, 7:30 P.M., February 9, 1909.

Professor W. C. Coker described a visit to Luther Burbank in his California home, illustrating his address with lantern slides and numerous specimens of Burbank's productions.

THE 182d meeting was held in the main lecture hall of Chemistry Hall, Tuesday, March 2, 1909, 7:30 P.M. The program was as follows:

Professor D. H. Dolley: "The Pathological Cytology of Surgical Shock: I., Preliminary Communication—The Alterations occurring in the Purkinje Cells of the Cerebellum."

Professor A. H. Patterson: "Exhibition of a Series of New Vacuum Tubes."

POST-GRADUATE STUDY IN APPLIED CHEMISTRY

THE subject assigned to me in this discussion seems to have been somewhat mixed. I have been asked to discuss:

1. To what extent is post-graduate training recognized or desired by employers of chemists?

2. What should be the attitude of technical interests toward post-graduate work?

3. What should be the attitude of technical institutions toward post-graduate study?

It matters little how the subject of our discussion is stated, it really becomes, What shall be the training or education of young men whose life work shall be the applications of chemistry, or physics, or both, in the industries? It is a question which the experience of a century at least has scarcely solved. The elements which enter into the answer are too varied, the results to be attained too manifold, the conditions available too perplexing, the personal equation too persistent. Shall the training be confined to the storage of the facts and laws of chemistry and physics in the minds and memories of the young students, trusting to the exigencies which may arise to find their application, and that when the exigencies do arise the facts and laws will be brought forth and be wisely applied? Or shall we first cause storage of facts, principles and laws, and afterwards offer training in the methods whereby these shall be applied and employed in the solution of the problems likely to arise in the industries and to demand treatment with satisfactory results?

Whatever may be said, the latter is what employers expect and demand. The questions which arise must be answered promptly and accurately. The amount of knowledge a man may have acquired and may possess is little appreciated unless it can be applied usefully and effectively. Complaint is not uncommon that young men from the technical schools are over-educated, overtrained; educated above and beyond the positions they must occupy and the work they have to do. While this is unfortunate in form of statement, it nevertheless expresses a fact. Many young men are profoundly educated in theories and laws and at the same time acquire little or no appreciation of the practical value of these theories and laws, even in the advancement of the science to which they relate, and certainly not in the solution of the problems of the industries and the arts of life. There is therefore, whether recognized or not, a demand for something beyond the regular course of study of the university or the technical school. Something beyond the mere cramming with facts and the academic training, to the exclusion of the systematic utilization of knowledge in the promotion of knowledge. Here then is the problem propounded to the educator for solution: How shall young men be educated and trained to meet the demands likely to be presented to them by the chemical industries? In the chemical industries it is natural that a profound knowledge of chemical laws should be required, but in addition to this there must be provided a sound knowledge of such laws of physics as may be necessary to the physical application of chemical laws. In the undergraduate school, first the laws of chemical action and the properties of matter, theoretical and descriptive chemistry, the methods of chemical analysis, qualitative and quantitative, must be taught, and it is

well known that one of the first steps in laboratory instruction in these methods is an introduction to the forms of apparatus to be employed in the practice of experiment and analysis. Then comes the application of the laws of chemistry and of the properties of matter to the methods of operation to be used. Now since manufacturing or industrial chemistry is really analytical chemistry in a large way, similar lines of instruction and training must apply in preparation for the industries. If acquaintance with the boiler, the condenser, the filter, the evaporating dish, the distilling apparatus, must be provided in the analytical and research laboratory; if here must be taught the sources and mode of application of heat; transfer of liquids, separation of vapors, liquids and solids; so all these processes made in a small way in the laboratories must be made large in the works. Operations made in a large way must be studied, and the means for effecting them made familiar. The operation of the chemist in the laboratory must become the operation of the engineer in the works. The industries demand that the men who shall control shall have some of that capacity known as engineering, shall know something of the materials and methods of engineering, of the larger apparatus to be employed and its management, and ability to apply the laws of physics in the larger operations of the works. Chemistry and engineering must, therefore, be combined in some measure at least, in the training of the men who will become most successful in meeting the demands of the "technical interests," and whether this is recognized generally or not, it is certainly desired by employers of educated chemists.

But the common complaint of the institutions and their teachers is, that the customary four years allotted to the undergraduate course is too brief for all

that is demanded and required. Here, then, is the problem to be solved: What shall be provided in the undergraduate course or school, and shall post-graduate study and training be provided and carried on under the direction and management of the educational institution, or shall the training, which might be provided by post-graduate study, be deferred and be supplied by actual practise in the works? How, and by whom, shall this very important question be answered? The demand of the present, and of the immediate future, is for men who are able to work independently, to take care of the problems arising, and work them out to successful issue, with profitable result. Directors in the industries and employers have little time, energy or freedom from detail, to devote to the training of young men in fundamental principles. Yet experience can be had only in practise, and this must be paid for in the time, energy and material apparently wasted by young men in the earlier periods of their life work.

But the question still persists. Could the young man working under intelligent direction in the systematic application of the principles he has been taught save time? Will the work of one, two or three years under intelligent and patient training of competent teachers save time of the young man and his employers and relieve both of embarrassment, loss and disappointment?

The laudation of the German chemical industry has extended to all nations, and is probably justified. In some of the most successful branches of the German chemical industry the practise is to take into the works only men who have served as *Privatdocent* in university or technical schools, and to become *Privatdocent* the candidate must generally have taken a course in post-graduate work in investiga-

tion and in the solution of problems; work leading to the doctor's degree. First, a training for systematic applied work, then experience in teaching. The value of the latter in the preparation of young men for life work is, I believe, too little recognized. It is certainly true that one of the most excellent means of securing a thorough and fundamental knowledge of a subject is found in an effort to impart such knowledge to others.

I have said elsewhere that an important adjunct to the successful application of knowledge is a trained imagination. Not an imagination "like the baseless fabric of a vision," nor "such stuff as dreams are made on," but an imagination based upon knowledge which furnishes a vision of what may be accomplished and suggests means for accomplishment.

So it seems to me that the proper function of the undergraduate school is to communicate knowledge of facts and methods and that the function of the post-graduate school is to furnish training in the application of knowledge to the solution of problems, to the training of the imagination, and thus to meet the demands which the industries, consciously or not, are making.

A most useful beginning in such work has been made in the laboratories for research in industrial chemistry lately established in some of the leading technical institutions. Here the subjects for research, the applications of knowledge, are not of an abstract but of a concrete character, and provide training in work which may produce results immediately useful in the arts of life. Here the problems arising in the industries in every-day work are solved by students, under direction of men who have themselves been trained in the solution of such problems. By such work the imagination is stimulated and at the same time trained and directed in proper channels; habits of application es-

tablished which must be fruitful later on. The designers of these laboratories, and the authorities who have ordered their organization and establishment, as well as the industries which have patronized and encouraged them, all deserve the highest praise. It is a step in the right direction, and one which must be taken in other educational institutions, if the proper and most effective training of young men for the industries is to be secured.

What then should be the attitude of the industries to post-graduate work? I answer unhesitatingly—*favorable*. What should be the attitude of the technical institutions to post-graduate work? I answer without hesitation, *favorable*. Post-graduate work should be earnestly encouraged from both sides, from the educational and from the industrial, and particularly from the latter. It has been fully recognized in the German institutions by providing in the technical schools courses leading to the degree of "doctor of engineering," and in the universities by the establishment of similar courses and providing for the same degrees. In all educational institutions the attainment of the degree of doctor—a degree not lightly appreciated nor glibly assumed in Germany—involves work of investigation leading to results, work devoted to the application of knowledge and the solution of problems. The industries in Germany are wise in choosing for their employees and directors those who have passed through the office of *Privatdocent* and have had, therefore, experience in the training and management of men. That men may become successful without this very extended and profound training is manifest in this country, and is due largely to the men themselves. But even such men would be better equipped for their work by the training provided by the undergraduate and post-graduate schools

and, though frequently compelled by their necessities to enter upon their life work without it, they would save much labor and loss of time to have had it. Many of those who, even with limited training in the schools, have been reasonably successful in the industrial, and in their life work in this country, have a right to speak feelingly and affirmatively upon this point.

May young men be overtrained? Surely—in the laboratories and in the class-room, as in the gymnasium and on the athletic field; and they may be weakened, from a practical standpoint, by their training. Yet even these are often carried by their enthusiasm to eminent success. "Fools rush in where angels fear to tread," applies equally well in the world of science and industry as elsewhere, and the struggle to get out after the rush in has produced some of the best results the world has seen, though the influence and the method may not always have been recognized or acknowledged. Each one who has had experience may furnish evidence of this fact. Effort to correct error of one's own making often leads to splendid results. "Necessity is the mother of invention," and the needs of a man in deep trouble make him devise means which otherwise remain dormant and without utilization. Yet errors should be avoided, and the more thorough training should lead to this.

Will the institutions meet this demand for better trained men? Will the new courses necessary to it be established? Of this there can scarcely be a doubt. The institutions are looking for the sign and will respond to it when it is plain. But what of the industries? Will the leaders make the sign prominent and clear? Will they do their share? Do they know what their share is? And do they appreciate their responsibility?

First, the institutions must know what is needed and the knowledge can be acquired only by close relations with the industries. Teachers should have ready access to the industries and their work for themselves and their students. Problems should be submitted for the research laboratories and needed means and materials provided. Such cooperation must certainly lead to important progress, not only in the industries, but in the related sciences, and progress under such circumstances is inevitable. May the influences which control have free course, and be not only justified but glorified.

WM. MCMURTRIE

THE PROGRAM OF THE INTERNATIONAL
COMMISSION ON THE TEACHING OF
MATHEMATICS¹

"If we could first know where we are and whither we are tending, we could better judge what to do and how to do it." These words of Lincoln, like the words of many another genius, adapt themselves to divers situations. This statement epitomizes what the International Commission on the Teaching of Mathematics is to do. The first purpose of this body is to investigate the actual state of the teaching of mathematics in the various countries, and the second purpose is to discover the tendencies of the changes effected during the last two decades. Both of these investigations are to be made with a view to determining "what to do and how to do it." In the language of the central committee the aim of the commission is to suggest those general principles which should guide the teacher rather than to provide programs which should be adapted at the same time to the schools of all countries.

To Professor David Eugene Smith, of Columbia University, belongs the credit of having first suggested the formation of such a commission in the French mathematical journal, *L'Enseignement Mathématique*, in

¹The complete Preliminary Report appeared in *L'Enseignement Mathématique*, and a translation by the author (of this article) in *School Science and Mathematics*, February, 1909.

1905 and again at the International Congress of Mathematicians at Rome in April, 1908. This congress authorized a committee consisting of Professor Felix Klein, Göttingen, Germany; Professor Sir George Greenhill, London, and Professor H. Fehr, Geneva, Switzerland, to form an international commission. Those countries which have been represented at certainly two of the international congresses of mathematicians, with an average of at least two members, are entitled to representation on the active membership of the commission, while other countries are invited to be represented by associate members. The national delegations are urged to affiliate with themselves national subcommissions, comprising representatives of the various stages of the teaching of mathematics in the general schools and in the technical and professional schools.

General direction is lodged in the original committee of three, Klein, Greenhill and Fehr. The official organ is *L'Enseignement Mathématique*, and the official languages are English, French, German and Italian.

The whole field of mathematical instruction, from the earliest primary work to the higher mathematics of the universities, is to be included in the investigation. A large place will be given to applied mathematics for technical and professional schools.

The work of the commission will be based upon the reports of the delegations, which are to be made out with the aid of the national subcommissions in conformity with the general plan fixed by the central committee of three. In the first part of these reports will be given a view of the actual scheme of studies, the corresponding examinations, the methods of teaching and the preparation of the teaching body. In the second part will be presented the actual tendencies of the instruction.

The aim of the mathematical instruction in the different types of schools—primary, secondary, trade schools, normal schools and teachers' colleges, and colleges and universities—will be discussed. Should the aim of the instruction be the development of the mathematical faculties, or logical reasoning, or

should the ends to be attained be purely practical?

Necessarily also some large educational problems are touched which concern the whole school organization. Mention may be made of the new types of schools and of the subject of coeducation.

The committee proposes to examine anew and with care what are the branches of this science most able to contribute to general culture. What is the necessary minimum in arithmetic, algebra, geometry and trigonometry, as well as in descriptive and projective geometry, analytic geometry and the calculus? What new ideas must be introduced and what old ones should be discarded?

The much-discussed laboratory method of teaching mathematics requires close inspection. Are there not inconveniences and dangers that result? In what measure may the conventional limits which exist between certain subjects of pure mathematics be made to disappear? What have been the results of the attempts to teach algebra and geometry together? geometry and trigonometry? differential and integral calculus? Careful study needs to be made of the points of contact of mathematics with drawing, with the applied sciences, with philosophy, and with the problems of daily life.

To what extent should paper-folding, observational geometry, logarithms, graphics in algebra and the slide rule be used? Those who desire a close relation between mathematics and physics ought to show exactly what geometrical notions have a direct bearing on physics and to cite those problems of elementary physics which require simultaneous linear equations, equations of the second degree in one or more unknowns, irrational quantities and progressions.

To what degree is it possible to accord a larger place to the historical development of mathematics and to the history of the teaching of mathematics? The extensive literature on mathematical recreations might be made useful. What are the means which will give mathematics a better place in popular instruction and enable the subject to overcome popular prejudices?

The progress of teaching depends directly on the preparation of the teachers. So the committee believes that it will be useful to take account of the reforms, actual or projected, which have in view the training of teachers conformably to modern conditions. In this connection the sex of the teacher for different schools, the introduction of the teacher to scientific research, and the amount of character of the pedagogical training are questions of fundamental importance.

The high plane of this investigation is indicated by the scientific standing of the three members of the central committee as well as by the personnel of the American delegation. These men are announced by Professor Klein to be the following: Professor William F. Osgood, Harvard University; Professor David Eugene Smith, Columbia University; Professor J. W. A. Young, Chicago University.

Preliminary work is to be begun immediately; the commission as a whole to meet during the Easter recess of 1911 preliminary to making a final report to the International Congress of Mathematicians, which is to meet at Cambridge, England, in 1912.

Some may regard the work of the commission as initiating a great reform movement. Reform does not come by commission; rather this development emphasizes the great movement towards vital instruction which has been in progress for over a century. The important work of the commission will be to gather together the valuable contributions from all the world and to make them available to all the world. To select the good and discard the worthless is no small task but one well worthy of the best efforts of the leaders in mathematical thought.

L. C. KARPINSKI

UNIVERSITY OF MICHIGAN,
ANN ARBOR, MICH.

LIEUTENANT SHACKLETON'S ANTARCTIC EXPEDITION

THE Wellington, New Zealand, correspondent of the *London Times*, has cabled some details of the scientific results of the Shackleton expedition.

The frozen glacier-eroded lakes near Cape

Royds abounded in diatoms, rotifers, water bears and infusoria. Numbers of rotifers which were examined microscopically had been frozen into the ice at temperatures below zero for three years; yet after a few minutes' thawing out they suddenly revived and began eagerly devouring the fungus which abounds in these lakes. In some cases only the body, not the head, of the rotifer appeared to come to life. Several rotifers were similar to those already described by Murray as having been found at Spitzbergen and Franz Josef Land. The water bears came to life in the same manner.

On the black lava rocks of Mount Erebus which had absorbed the sun's heat the snow melted at temperatures below zero and at a height of 9,000 feet. This explains how lichens and similar plant life are enabled to flourish in the Antarctic regions.

The marine fauna near Cape Royds bears a resemblance to the types of animal life of the coal measure series found in Australia and Tasmania. Specimens will be examined by scientific specialists in New Zealand and Australia.

The northern expedition found masses of marine muds 40 feet above the sea level. These contained vast numbers of foraminiferal shells. The biloculina type, which form the biloculina ooze of the Arctic Circle, are specially abundant.

The geological discoveries disprove the Antarctic archipelago theory. The continental plateau extends from the newly discovered mountains 45 miles west of Cape Royds and the magnetic pole to beyond the south pole itself, probably over 1,800 miles. By far the most interesting geological discovery is that of coal measures in latitude 85°; these measures 1,500 feet thick, contain seams of coal 1 foot to 7 feet thick. The microscopic examination of the mineral charcoal which has been secured may indicate its geological age. Rounded quartz pebbles and the great thickness of the sandstone formation imply the action of running water prolonged through many ages. The limestone discovery at the farthest south, interstratified with a remarkable rock of pinkish gray, branded with dark green, un-

like any that Professor David has ever seen, may prove important under microscopic examination. The ancient rocks examined apparently contain monazite.

Near Mount Larsen an interesting deep green mineral was found, which is almost certainly a compound of vanadium. Mount Erebus, like Stromboli, proved a good barometer, the steam column ascending and eruptions occurring with a low barometer. At periods the active crater contained molten lava. The old crater was filled almost to the brim with layers of snow. There are millions of felspar crystals 8 inches to 4 inches long, and pumice lava is of a rare kenite type. Fossil radiolaria were found in erratics of banded chert near Cape Royds. Lieutenant Shackleton is sending specimens of all these rocks to the British Museum. The exact location of the magnetic pole was fixed by elaborate triangulation by Mr. Mawson, extending over 200 miles from Mount Erebus to Mount Melbourne. It proved that the magnetic pole is no longer moving eastward as in Ross's time, but is now traveling northwestward in much the same direction as the north magnetic pole.

The summit crater of Mount Erebus was very active as regards steam and sulphur gases. No molten lava was seen, but during a big eruption in June and until September the steam column was glowing like a huge beacon fire, indicating that there was molten lava in the crater. Recently ejected "bombs" were found lying on the new snow, large quantities of sulphur being formed in the crater.

The coal measures discovered far south are probably older than the Tertiary Period; indeed, judging from the induration of the rock, they apparently date back to paleozoic times. No fossils to settle the point have been found, but a microscopic examination of the specimens may solve the problem.

THE RESIGNATION OF PRESIDENT ANGELL

THE regents of the University of Michigan have passed the following resolution:

This board has received with regret the assurance of our beloved president, Dr. James Burrill

Angell, that the time has come when, in his judgment, he should be permitted to retire from the active direction of the affairs of this university.

We desire to record here and now some measure of our appreciation of his services to this institution, of which he so long has been the head.

It is now nearly thirty-eight years since he assumed the presidency of this university. Under his leadership it has grown in student attendance from about 1,200 to more than 5,000, with a corresponding increase in faculty membership. Its advance in effectiveness of educational work and in all that goes to make a university great has been no less prominently marked. The proud position which this university has attained is due, more than to all other elements combined, to the fact that for more than one half its entire life it has been blessed with his learning, his culture, his wisdom, his tact, and, above all, with the example and inspiration of his high-minded Christian character.

It is impossible to calculate the impress for good given to the world by the 40,000 men and women who have carried with them from this institution into their work and in their lives the commanding influence of his rich character and personality.

Proud as he may justly be of the homage which the world justly yields him as educator, diplomat and publicist, he has even greater cause for pride in the grateful affection of the people of this state, whom he has served so long and so abundantly, and in the love of the army of students, whose lives he has directly enriched and to whom he will always stand for all that is highest and best in scholarly attainments, in private character and in public and private citizenship.

The women of the University of Michigan, at their annual banquet, held at Barbour Gymnasium on April 2, passed resolutions, the first part of which read:

This occasion on which you, in your official capacity, address for the last time the body of women of the University of Michigan marks an era in the higher education of women, not alone in this commonwealth, but in America. Your assumption of Michigan's responsibilities was contemporary with our entrance into its opportunities. We were a hazardous experiment given into your hands in the face of a skeptical world. There are no adequate words to express our gratitude for your unswerving loyalty to that trust. We give you increasing homage and reverence for the gifts of genius with which you have wrought

in our behalf. Yours has been, for two score years, the most potent influence in the land for the unrestricted privilege of higher education for women; yours the simplicity before which self-consciousness vanished; yours the fine courage that has helped many a sinking purpose to effective conclusion; yours the felicitous word that has parried the criticism of an over-expectant world, and has signally won where more militant methods would have lost.

SCIENTIFIC NOTES AND NEWS

THE spring meeting of the council of the American Association for the Advancement of Science will be held in the Assembly Hall of the Cosmos Club, Washington, D. C., on the afternoon of Wednesday, April 21, 1909, at 4.30 o'clock.

THE annual session of the National Academy of Sciences will be held in Washington, D. C., beginning Tuesday, April 20, 1909, at 11 A.M. The place of meeting will be the Smithsonian Institution. The public sessions for the presentation of scientific papers will be held in the large hall of the National Museum on Tuesday and Wednesday afternoons, April 20 and 21.

THE American Philosophical Society, Philadelphia, will hold a general meeting on April 22, 23 and 24. The opening session will be held on Thursday afternoon, at 2 o'clock in the hall of the society in Independence Square. A Darwin commemoration will be held on Friday evening at 8 o'clock in the Hall of the Historical Society of Pennsylvania followed by a reception. The afternoon session on Saturday will be devoted to a symposium on earthquakes. The annual dinner of the society will be held at the Bellevue-Stratford, on Saturday evening.

PROFESSOR T. G. BONNEY, F.R.S., will succeed Professor J. J. Thomson, F.R.S., as president of the British Association and will preside over the meeting to be held at Sheffield next year.

THE London Geographical Society has awarded its Victoria Research medal to Mr. Alexander Agassiz. The society has awarded a special medal to Lieutenant Ernest H. Shackleton.

THE John Fritz medal for 1909 has been awarded by the committee of the national engineering societies to Mr. Charles T. Porter, of Montclair, N. J., for his work in advancing the knowledge of steam engineering and in improvements in engine construction, especially in high speed engineering. The first medal was awarded in 1903 by the board of award organized by the admirers of Mr. John Fritz, the eminent engineer, on the occasion of his eightieth birthday. The other recipients thus far have been Lord Kelvin, Thomas A. Edison, Alexander Graham Bell and George Westinghouse.

THE Mikado of Japan has bestowed on President Eliot the decoration of the Order of the Rising Sun, first class.

MANCHESTER UNIVERSITY has conferred its doctorate of laws on Professor Walter Baldwin Spencer, professor of biology in the University of Melbourne and known for his anthropological researches on the native tribes of central Australia.

PROFESSOR FERDINAND ZIRKEL, for nearly forty years professor of mineralogy and petrography at Leipzig, has retired from active service.

DR. JULIUS HANN, professor of cosmical physics at Vienna, has celebrated his seventieth birthday.

AT the meeting of the American Association of Pathologists and Bacteriologists, held last week at the Harvard Medical School, Dr. Frank D. Mallory, assistant professor of pathology of the Harvard Medical School, was elected president for the meeting to be held next year at Washington.

PROFESSOR F. D. FULLER, chief chemist, Pennsylvania Department of Agriculture, Harrisburg, Pa., has been appointed chief of the cattle food and grain investigation laboratory, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C., and assumed the duties of his position on April 1.

UNIVERSITY COLLEGE, Oxford, has awarded the Radcliffe prize for 1909 to Mr. Arthur Frederick Hertz, Magdalen College, for his dissertation on the physiology and pathology of the movement of the intestines.

DR. HERMON C. BUMPUS, director of the American Museum of Natural History, has received letters from Dr. R. M. Anderson and Dr. V. Stefansson, explorers for the museum on the extreme north coast of Alaska. The letters were dated October 15.

Two assistant curators of the Field Museum of Natural History, Messrs. S. C. Simms and F. C. Cole, are to take up the ethnological investigation in the Philippines interrupted by the recent murder of Dr. William Jones.

THE Phi Beta Kappa address at Columbia University will be given by Dr. A. Lawrence Lowell, president-elect of Harvard University.

SEÑOR JOAQUIM NABUCO, ambassador from Brazil to the United States, will deliver the baccalaureate address at the University of Wisconsin.

DR. GEORGE H. PARKER, professor of zoology at Harvard University, gave a series of six lectures at the University of Illinois, March 29 to April 3, on the subjects of coral islands, the functions of the ear in fishes, and the origin of the nervous system.

THE third meeting of Research Workers in Experimental Biology, of Washington, D. C., was held at the Medical Department of George Washington University, on April 3, when Dr. Leo Loeb, assistant professor of experimental pathology in the University of Pennsylvania, read a paper on "The Experimental Production of Maternal Placenta."

SIGMA Xi Honorary Fraternity at the University of Pennsylvania initiated its new members in the Randal Morgan Laboratory on April 7. Previous to the exercises old members and new assembled in the auditorium, where Mr. H. Clyde Snook, of New York, delivered a lecture on "The Mechanical Rectification of One Million Volts."

THE Woman's College, Baltimore, in conjunction with a committee of the alumnae association, has arranged a course of lectures on "Nutrition." The first were given last week by Dr. William J. Gies, of the College of Physicians and Surgeons of New York. Other lecturers are to be: Dr. Henry C. Sherman, New York; Dr. William H. Howell, Johns

Hopkins University; Dr. H. P. Armsby, State College, Pa., and Dr. C. W. Stiles, Washington, D. C.

THE Oliver-Sharpey lectures of the Royal College of Physicians, London, have been given by Professor C. S. Sherrington, F.R.S., on "The Rôle of Reflex Inhibition in the Co-ordination of Muscular Action."

PROFESSOR HENRY JONES, on behalf of a committee, appeals for funds towards a memorial of the late Dr. Edward Caird in the University of Glasgow—to place an inscribed tablet in the moral philosophy classroom, and to supplement the endowment of the lectureship in political philosophy.

THE regents of the University of Kansas have named the entomological collections of the university the Francis Huntington Snow Entomological Collections, in honor of the late chancellor of the university.

DR. PERSIFOR FRAZER, well known as a chemist, geologist and mining engineer as also for his studies in handwriting, died at his home in Philadelphia on April 7, at the age of sixty-three years. Dr. Frazer had been connected with the United States and Pennsylvania Geological Surveys and was at one time professor of chemistry in the University of Pennsylvania. His father was professor of natural philosophy and chemistry in the university and one of his sons is now instructor in chemistry in the institution.

MR. CHARLES ALDRICH, a fellow and one of the founders of the American Ornithologists' Union, died at Boone, Iowa, on March 8, at the age of eighty years. In addition to ornithology, Mr. Aldrich was interested in local history and had been curator of the State Historical Department at Des Moines, Iowa.

DR. ARTHUR GAMGEE, F.R.S., emeritus professor of physiology, University of Manchester, and late Fullerian professor of physiology in the Royal Institution, died in Paris on March 29, aged sixty-seven years.

DR. VAN HEUVER, director of the Zoological Gardens at Antwerp, has died at the age of seventy-one years.

DR. LUDWIG THANHOFFER, professor of anatomy at Buda Pesth, has died at the age of sixty-six years.

THE U. S. Civil Service Commission announces an examination on April 21, to fill three or more vacancies in the position of laboratory assistant (in chemistry) and assistant chemist in the Bureau of Standards, at salaries varying from \$900 to \$1,200 per annum for laboratory assistant, and from \$1,400 to \$1,800 per annum for assistant chemist. The duties in connection with these positions vary from routine testing to advanced work involving original investigation. As far as practicable, appointees are assigned to work in the subjects for which they are best fitted.

THE *Bulletin* of the American Mathematical Society states that the Deutsche Mathematiker-Vereinigung now includes 725 members, of whom 60 are Americans. The Circolo Matematico di Palermo has a membership of 635, of whom 105 are Americans.

THE annual meeting of the German Bunsen Society of Applied Physical Chemistry is to be held at Aachen on May 23-26, immediately before the International Congress of Applied Chemistry in London.

UNDER the will of Elizabeth F. Noble, of Mansfield, Mass., bequests of \$10,000 each are made to the American Society for the Prevention of Cruelty to Animals and the American Anti-vivisection Society, \$5,000 goes to the Massachusetts Society for the Prevention of Cruelty to Animals, and after other sums are paid, the three societies are to share in the residue of the estate.

THE daily papers state that the Jesuit Fathers have decided to install a complete apparatus in twelve colleges belonging to their order in this country to take earthquake records.

PLANS are maturing for a large exposition to be held in Buenos Ayres in May and June of 1910, on the occasion of the centennial celebration of the independence of the Argentine Republic.

ALL paleontologists are interested in the discoveries in the Permian of northern Russia,

and are awaiting eagerly publication of the results arrived at by Professor Amalitzky. The kinship which these remarkable animals bear to those of the Permian of North America and of South America renders the problem one of international importance. The only figures which have been published are those which appeared through the courtesy of Professor Amalitzky in a popular work by Sir Edwin Ray Lankester. All the collections have now been transferred to the Museum of the Academy of Sciences of St. Petersburg, which will be their permanent home. Professor Amalitzky is, however, the director of the Polytechnic Institute of Warsaw.

ILLUSTRATED lectures will be delivered in the lecture hall of the museum building of the New York Botanical Garden, Bronx Park, on Saturday afternoons, at four o'clock, as follows:

April 24—"A Winter in Jamaica," by Dr. William A. Merrill.

May 1—"Spring Flowers," by Dr. Nathaniel L. Britton.

May 8—"How Plants Grow," by Dr. Herbert M. Richards.

May 15—"Evergreens: How to Know and Cultivate Them," by Mr. George V. Nash.

May 22—"Collecting Seaweeds in Tropical Waters," by Dr. Marshall H. Howe.

May 29—"Vanilla and Its Substitutes," by Dr. Henry H. Rusby.

June 5—"The Selection and Care of Shade Trees," by Dr. William A. Merrill.

June 12—"The Ice Age and Its Influence on the Vegetation of the World," by Dr. Arthur Hollick.

June 19—"Haiti, the Negro Republic, as seen by a Botanist," by Mr. George V. Nash.

June 26—"Some American Botanists of Former Days," by Dr. John H. Barnhart.

July 3—"An Expedition up the Peribonca River, Canada," by Dr. Carlton C. Curtis.

July 10—"Collecting Experiences in the West Indies," by Dr. Nathaniel L. Britton.

ACCORDING to the New York *Evening Post* a valuable archeological collection has recently been installed in the museum at Vanderbilt University as the gift of General Gates P. Thruston. The relics include specimens from Tennessee, Missouri, Arkansas and other southern states and Indian relics from Peru.

A number of specimens were taken from mounds near Nashville, Tenn., and show such skill as to point to some higher civilization than that of the Indians who dwelt there in historic times. The Peruvian relics show so close a resemblance to these remains that the theory of kinship between the makers of this pottery and the people of Peru has been advanced. In addition to the Indian relics, there are many minerals, gems and semi-precious stones. The collection is arranged in a room of University Hall to be known as the "General G. P. Thruston Room."

A NEW index map of Alaska, showing areas covered by topographic surveys, has been issued by the U. S. Geological Survey. On the back of this map is printed a list of the survey's publications on Alaska, arranged geographically. These publications comprise 28 maps and 119 reports. The work of the Geological Survey in Alaska, begun in 1898, has been indispensable to the development of the mineral resources of the territory. The value of the mineral output of Alaska to date is approximately \$148,000,000, including the values of gold, silver, copper, coal, tin, marble and other minerals. The cost of the survey's explorations in the territory has been less than three tenths of 1 per cent. of the total value of the mineral productions. Since 1898 areas in Alaska amounting to 121,252 square miles have been topographically surveyed on a scale of four miles to the inch and 2,732 square miles on a scale of one mile to the inch. These surveys cover, respectively, 20.85 and 0.47 per cent. of the total area of Alaska, which is 586,400 square miles. During the same period geologic reconnaissance maps have been made of 99,350 square miles and detailed geologic maps of 2,304 square miles. In addition to this work, practically every mining district in Alaska has been examined, and some have been mapped in great detail. The water resources of some of the important placer districts have also been studied and the results published.

On the invitation of President Edmund J. James, a conference was held at the University of Illinois on March 31. The conference considered the needs of the state in out-of-door improvement, both for the home and the

municipality and a state organization for this purpose was effected. The following objects and plans were considered:

1. To circulate information through publications originating with the organization and wherever procurable. These should discuss topics upon which the people want information, the kinds and uses of ornamental plants, insect enemies, the arrangement of the farm and suburban home, the practical problems of street, play ground, park and cemetery development, the customary methods of improvement organizations and kindred subjects.

2. To promote, where requested, the formation of village, municipal and neighborhood improvement and similar societies, park boards and park-way associations and to assist them within its field.

3. To advise upon the instruction of landscape gardening and ornamental horticulture, both professional and elemental in the University of Illinois and to assist in similar courses given elsewhere in the state.

4. To contribute lectures upon the subject throughout the state when requested.

5. To advise upon experiments in the hardiness and usefulness of ornamental plants in the different latitudes of the state and to encourage the creation in some form of small public plant gardens where the ornamental use of trees, shrubs and flowers can be readily studied.

6. To frame and secure necessary legislation which shall promote out-of-door art.

A COLLECTION of British birds' eggs has been presented to the Natural History Museum of Aberdeen University by Mr. R. Hay Fenton, London, a native of Aberdeen. The collection contains specimens of practically every British bird, and includes an egg of the great auk. It numbers upwards of 7,000 specimens.

THE American Museum of Natural History has recently acquired, through purchase from Mr. G. R. Cassedy, of Cañon City, Colo., an iron meteorite that will form a valuable addition to the series of meteorites in the foyer of the museum. The specimen, which weighs 682 pounds, was found November 11, 1907, in Fremont County, Colorado.

PROFESSOR W. M. DAVIS, of Harvard University, read a paper on March 22, before the Royal Geographical Society, London, on "The Colorado Canyon." At the meeting of the so-

ciety on April 5, Sir Harry Johnston gave a lecture on the scenery of Cuba, Haiti and Jamaica, with illustrations from photographs taken by him.

WE learn from the London *Times* that the members of the committee of the ill-fated Danmark Arctic expedition have raised a sum of £1,250, which, if the government will provide a similar amount, will be sufficient to despatch a small motor-yacht expedition to northeastern Greenland to search for the diaries and sketches probably left at Danmark Firth by M. Mylius Erichsen, the leader of the Danmark expedition, and his companions MM. Brönlund and Hagen, who perished in an attempt to cross the inland ice in winter. The plan was set on foot by the well-known Arctic explorer Captain Ejnar Mikkelsen, who will be the leader of the new expedition, which, according to the intentions of the committee, will consist of seven persons, and will start from Copenhagen about June 15, 1908, returning in the autumn of 1910.

WE learn from the London *Times* that the British Ornithologists' Union has decided to undertake a zoological exploration of the interior of Dutch New Guinea. Dr. Lorentz, who is once more on his passage out to New Guinea, has been recently up the Noord River, and mapped some of the ranges lying south of the Charles Louis Mountains, but his aims were geographical rather than zoological. The direct objective of the new expedition will be the Charles Louis Mountains, a snow-capped range forming part of the great central system stretching across the island from east to west. These are the Snow Mountains of the Dutch, and the highest peak is given on the most recent map as 17,000 feet. It is proposed that the expedition shall leave England about June, and every endeavor will be made to provide for a clear year's work. Mr. Walter Goodfellow, whose name is known from his collecting journeys in New Guinea, will be in command of the expedition, and his assistants, Mr. Stalker and Mr. Wollaston, have had some previous experience in the island. To these it is intended to add two specially-selected men, so that all branches of zoology and botany, and also of geography, may be

represented. Mr. Stalker is now on his way to the Aru Islands, where he will collect for Sir William Ingram, for whom, it will be remembered, he brought home the Prince Rudolph bird-of-paradise, which was exhibited at the Zoological Gardens last year. When his contract with Sir William is completed he will go over to the Ke Islands, and work there till the arrival of Mr. Goodfellow's party in New Guinea, when a start will be made from the south coast, just under the highest-known point of the central range. A small committee, consisting of Dr. F. D. Godman (president of the British Ornithologists' Union), Dr. P. L. Sclater (editor of the *Ibis*), Mr. E. G. B. Meade-Waldo, Mr. C. E. Fagan (treasurer) and Mr. W. R. Ogilvie-Grant (secretary), will deal with the results of the expedition. The expenses for one year's exploration have been calculated at £3,000, of which about half has been subscribed or promised.

UNIVERSITY AND EDUCATIONAL NEWS

THE legislature of Nebraska made appropriations for the State University for the biennium 1909-11 as follows: from the "one-mill university levy," for general expenses, salaries, etc., about \$750,000; from the general fund—for a site for the medical college, \$20,000; for experimental sub-stations (3), \$45,000; for farmers' institutes, \$20,000; for permanent improvements, additional land, etc., \$100,000.

THE following letter has been addressed by Mr. Andrew Carnegie to the president of Hamilton College:

In recognition of the unique services of Elihu Root as Secretary of State in the cause of international peace, through arbitration treaties negotiated by him, and in various other directions, I give the sum of \$200,000 to Hamilton College, the institution of which he and his two brothers and also his two sons are graduates, and of which his father was so long a distinguished professor. In accordance with the wish of Mr. Root, this sum is to be held and invested by the trustees of the college as a trust fund, the income to be devoted to the salaries of the instructors of the college. It is to bear the name of the Elihu Root Peace Fund.

OUT of the \$260,000 recently secured by Knox College (\$50,000 from the General Education Board, \$50,000 from Mr. Carnegie and \$160,000 from the alumni and friends of the institution), \$50,000 is to be used in building a Science Hall. It is expected that work will begin on this building the present season.

THE last legislature appropriated money to establish six new graduate fellowships at \$500 each at the University of Kansas. They are open to teachers in Kansas colleges and to superintendents and principals of Kansas schools, who are graduates of colleges and universities of recognized standing and who have shown preeminent qualification for advanced work. A large glass company with head offices in New York City has offered \$1,500 a year for two years for a fellowship for a research student working on "The optical properties of glass in relation to its chemical constitution."

MR. F. G. THOMPSON, of the class of 1897, has presented Harvard University with \$50,000, for salaries in the department of history and government.

THE directors of the Krupp's Works at Essen have made an annual grant of 10,000 Marks for the aeronautic professorship at Göttingen University, to be devoted to research work connected with aeronautics.

ON recommendation of the chancellor and regents of the University of Nebraska, the legislature of the state has amended the charter of the institution so as to allow the regents to establish the following colleges, viz: (1) The Graduate College; (2) The College of Arts and Sciences; (3) The College of Agriculture; (4) The College of Engineering; (5) The Teachers College; (6) The College of Law; (7) The College of Medicine. The first named, which has hitherto been called the Graduate School, is now raised to the dignity of a college. The name of the second college has been shortened from College of Literature, Science and the Arts, to College of Arts and Sciences. The third and fourth colleges have hitherto constituted the Industrial College, and this name will now disappear, giving place to the colleges of Agriculture and of Engineering.

In the Nebraska legislature the joint resolution accepting the Carnegie pensions for the State University was defeated, although it was passed in the senate by a vote of 25 to 8. In the house it was opposed by Mr. W. J. Bryan, and was lost by a vote of 47 to 51. The matter now goes over to the next legislature.

THE University of Colorado Mountain Laboratory, a department of the university's summer school, opens a six-week session on June 14, under the direction of Dr. Francis Ramaley. It is situated at Tolland, Colo., at an altitude of 8,889 feet. Courses are offered in general biology, nature study, plant ecology, anatomy and taxonomy and special lectures will be given on forestry, ornithology, physiology, climatology, glacial geology, photography and map-making.

THE Rev. Dr. Marion Leroy Burton, pastor of the Church of the Pilgrims, Brooklyn, has been offered the presidency of Smith College, to succeed the Rev. Dr. L. Clarke Seelye.

At the College of Physicians and Surgeons, Columbia University, Dr. R. Burton-Opitz, adjunct professor of physiology, has, on the retirement of Professor John G. Curtis, been appointed head of the department of physiology. In the department of the practise of Medicine, Dr. Walter B. James has, at his request, been transferred from the Bard professorship, which involved the administration of the department, to a professorship of clinical medicine, and Dr. Theodore C. Janeway and Dr. Evan M. Evans, now associates in medicine, have been promoted—Dr. Janeway to the Bard professorship and Dr. Evans to a newly created professorship of clinical medicine.

DR. GEORGE H. LING, of the department of mathematics, Columbia University, has been advanced to the rank of adjunct professor.

At Cornell University, Professor H. H. Norris has been appointed professor of electrical engineering in charge of the department.

THE professorship of physics at Lafayette College, made vacant by the death of Professor James W. Moore, M.D., has been filled by the appointment of Professor Clarence McCheyne Gordon, Ph.D., now professor of

physics at Center College of Central University, at Danville, Ky.

DR. HERMANN DÜROK, of Munich, has been appointed professor of pathological anatomy at Jena.

DISCUSSION AND CORRESPONDENCE

WILLIAM KEITH BROOKS

TO THE EDITOR OF SCIENCE: Professor Andrews's tribute in your issue of December 4, 1908, gave the first sad intimation to western readers of the death of Dr. Wm. K. Brooks, and very acceptable information concerning his later years, much of which was news to the present writer by reason of enforced separation in work and experience. Knowing thoroughly the innate worth of the man, from intimate relations as a companion of early youth, neighbor, schoolmate and associate in early scientific work, I am minded to record a few facts which have direct bearing upon the cost to himself of Brooks's contributions to biology.

In all his training at home, in school and at college, he was rigidly surrounded with influences adverse to original research or to scientific study. His mother died before his bent had become sufficiently pronounced to arouse opposition, and it is doubtful if she would have essayed to thwart him, for she was a lady of rare qualities and keenly sympathetic with her children's dispositions. His father and his stepmother were strong adherents to the unyielding utilitarian ideas of the times, and could not then recognize the full meaning of the struggle of the youthful mind.

In 1875, near the period of culmination of the strife engendered by Darwin's work, it was no light thing to withstand the well-meant resistance of good friends who could see naught but wickedness in the new ideas. Then Brooks's character shone brightly to those who knew him best. It was, perhaps, a very little result which came from the session of the Kirtland Summer School of Natural History, in Cleveland, in that year. But it signified much more than was apparent. It was the outcome of many earnest discussions by Brooks and the writer, after some consultation

with the then aged Dr. Jared P. Kirtland. We decided to ask the Kirtland Society of Natural History to act as sponsor for our plans. Although this was conceded, and an effort was made to finance the project, it was but a gloomy outlook before the volunteer instructors when the students began to register. Albert H. Tuttle, now professor in the University of Virginia, Wm. K. Brooks and the writer, all then earning a scanty living by work not germane to the task, came before the little band of students almost empty handed. Certain influential members of the Kirtland Society had successfully prevented our use of the society's working rooms, on the ground that the smells and refuse from dissections would annoy other tenants and injure the building. The officers endeavored to raise funds, but the subscription papers headed by them were signed for such small sums that those who might otherwise have given more freely were limited by them. The money actually secured would not cover the cost of collections, to say nothing of freight and other expenses. We decided to put on a bold front, and to start with such home material as we might individually collect or purchase in local markets. But it was found impossible to rent other quarters, owing to prejudice against our "bloody" work. After anxious consultations, the plan suggested by Brooks was adopted. We would hold field sessions and depend upon enthusiasm and contact with nature to somehow work out results. As a last resort, it might be possible to utilize the barn of good old Dr. Kirtland, miles out in the country.

At this juncture there came forward keen-sighted men whose memories should be revered by all who have made sacrifices for science. Andrew J. Rickoff, then superintendent of schools of Cleveland, urged the board of education to offer free use of the Central High School Building and its appurtenances to us, as three of its former pupils, during the vacation. A resolution was passed, referring the matter to the superintendent of buildings, with power, provided that all damages accruing from dissections, etc., be made good by the summer school. There were pressures of the

hand, words of encouragement and quiet exercises of influence from the great-hearted Rickoff which gave inspiration to Brooks in his splendid work of that summer. Leonard Case, owner of the building occupied by the Kirtland Society, had at first approved the use of the society rooms by the school. The adverse influences, and more particularly the objections of tenants, had caused him to rescind this privilege. He had not personally subscribed to the sustaining fund, and no one regarded him as in any way favorably inclined to our project. It was a gloomy outlook which confronted the instructors on the day before the opening, when only three teachers (from Indianapolis) had registered (Dr. David Starr Jordan was probably responsible for these). The writer, as editor of a "science column" in the *Cleveland Herald*, had published widely the plans and this appeared to be the sole outcome of months of labor and sacrifice. Mr. Benedict, proprietor of the *Herald*, and J. H. A. Bone, its talented editor, had given warm support liberally in print and by those little words which lie stored forever in memory. But to Brooks and us the apparent misunderstanding of Leonard Case was a most disheartening blow.

I can never forget the conference with Brooks in the office of the Kirtland Society, where the gross results were canvassed towards evening of that day. In words like these he spoke: "I am glad there are three of them—one apiece, all women. What could we have done—we three—if there had been but one? Three teachers, well trained, means the sowing of seed which shall yield a harvest none can measure."

We parted for the night. Left alone and heartsick, I saw Leonard Case enter the room as if he were about to do something mean. He asked "How did you come out?" "Oh, fairly," was the reply. "I don't suppose you got any too much for collections and excursions, did you?" He was told that we could manage somehow. Then he blushed and appeared ill at ease, remarking that he had regretfully kept us out of the rooms and that he had watched our work and knew with whom

he was dealing. "I don't believe you will have any trouble in finding use for a little more. Here is a trifle for you to apply, on just one condition. Put it in your pocket and expend it as you choose. Make no note of it in your accounting." He left, with a rough yellow envelope sealed in my hands. This contained seven bills of \$100 each. The total contributions raised outside of this did not amount to \$200, as I recall.

And the school grew. The work of Brooks was prophetic of his future career. Collections and excursions and dissections were made possible. Dr. John S. Newberry gave us two lectures on geology which were beyond and above any I ever heard for concise completeness. If from this poor little effort there came forth no other good than the launching of Brooks upon his most worthy career, it is honor indeed to have shared in the cost thereof.

THEO. B. COMSTOCK

LOS ANGELES, CAL.

SCIENTIFIC BOOKS

Histologisches Practicum der Tiere. By DR.

KARL CAMILLO SCHNEIDER, A. O. Professor in the University of Vienna. With 424 text-figures. Jena, Gustav Fischer. 1908.

In view of the excellence of the first edition of K. C. Schneider's histology, which appeared about six years ago, students of the subject will welcome this new edition recently published by Fischer in Jena. The wide circulation of the first edition, together with the importance attached to it by all scientists, will enable the writer to more easily review the last edition by some slight reference to the first.

In general, it may be said that the author has endeavored, by shortening his "*Lehrbuch der vergleichenden Histologie*," and by slightly rearranging it, to make it more practical and to adapt it to the use of university students taking a "course" in the subject. While doing this, some of the subject-matter has been rewritten to accord with the results of recent research, and some entirely new work has been added.

The first or general part of the work opens, after the preface, with an introduction, in

which the subject is defined and the view-point and method of treatment outlined. This discussion is concluded (p. 5) with two ideas which give the author's conception of histology and, of necessity, fix the form of arrangement of the whole book. The first idea is that histology should concern itself only with structure or form and should be studied and treated without regard to function. Secondly, that, being a fundamental morphological study, it underlies any natural scheme of classification. The reviewer presumes that by "natural classification" is meant the classification founded upon blood relationship through evolution.

The reviewer does not wish to criticize this conception as the guiding principle in a histological course, being fully impressed with its educational value in a book so well executed as that under review. He does, however, wish to call attention to another view, held by some workers including himself, which looks upon histological structure as the important machinery through which the varied functions of organisms are performed and life is maintained. Such a view, which lays special stress on the cytological and chemical side of histology without making it altogether a study of physiology, has prompted the writing of such text-books as Prenant's "*Traite D'Histologie*" and Martin Heidenhain's "*Plasma und Zelle*." The introduction concludes with a discussion of some of the principal features of animal morphology or "*Architektonik*," followed by a systematic arrangement of the animal kingdom on this basis.

The remainder of the "general part" is taken up with an account of the structure of the cell, of cell division, and of the working substances of the cell; also a special account of the various groups of cells (under eleven types) and a very short account of some general principles of tissue and organ building, this latter being the last of the "general part" of the work which occupies 75 pages out of the entire 518 in the volume. When we notice that this "general part" occupied 240 pages in the former edition instead of 75, it can be seen how greatly this portion of the present edition has been reduced. This reduction has

been effected, chiefly, by cutting out about 80 pages on special organology, and 60 pages on "Architektonik" or morphology; also by omitting many figures and parts of the descriptive matter, as well as changing other parts. Some new paragraphs, mostly of a historical nature, have been inserted.

The second part of the book or "special part" deals with the descriptive histology of some 40 animal types taken in almost systematic order. The entire histology of each form is seldom discussed, but only such portions as are characteristic, or as fill out gaps in the rather rough and incomplete system of tissue classification, are described in the author's thorough and scholarly way. The whole part is divided, very arbitrarily, into 50 lessons as a convenience to teaching.

This special part is, of course, the largest and most substantial part of the book. To estimate very crudely the amount by which it has been reduced from the corresponding part in the old edition, it may be said that in the latter it occupied 685 pages, while in the new form it is contained in 445 pages. This reduction has been secured by taking out descriptions of a few entire forms and of certain of the tissues of other forms. Care has been shown in doing this, as a rule, to remove those parts which in any sense duplicated or paralleled other parts.

Comparatively little has been added to this part of the book, although it has been carefully worked over and much changed in many details. One improvement consists of the addition in several places of appropriate details of histogenesis. The omission of any allusion to the comparatively rare but important tissues that produce light and electricity is a disappointment to the reviewer; the more so that other rare tissues of possibly less fundamental importance have been left in, as a quite extensive account of the structure and development of the nettle cells of *Physophora*. All reference to gas secretion has been omitted, although it was treated of in the first edition and is a matter of scientific importance.

The index is short, too short even when one considers that the method of arrangement and table of contents both supply much that is

omitted in its numbers. As an instance, a student or research man would have to search through nine pages of text to find the concise but valuable account of muscle structure in *Peripatus* (pp. 131-132), there being no indication of this item in index or table of contents. Were he to start on a comparative study of muscle he would have to search carefully in other places as well. This also holds true for other tissues.

Personally the writer would have preferred to see an enlarged edition of the former "Lehrbuch," strengthened by certain additions and revisions. One can not help feeling that the new edition is, in part, a sacrifice of scientific ideals to practical or even commercial demands. An advanced student should really have the old edition as well as the new, even if he should not prefer the first edition outright. It is to be hoped that the author will, in the near future, give to advanced students of scientific histology a third and fuller edition.

The printing, figures and general make-up are all that can be desired, and the very few errors of typography and lettering are a negligible quantity; the bibliography is full and complete. The book should be in the hands of every advanced student of histology as well as of other zoological subjects.

ULRIC DAHLGREN

Probleme der Protistenkunde. I. Die Trypanosomen ihre Bedeutung für Zoologie, Medizin und Kolonialwirtschaft. Von F. DOFLEIN, Ao. Professor der Zoologie an der Universität München. Jena, Gustav Fischer. 1909. Pp. 1-57.

Under the above title there has appeared an excellent article on the present knowledge concerning trypanosomes.

The trypanosomes are small one-celled animals bearing a flagellum on one end and an undulating membrane on the side of the body. They are classed under the protozoan group Flagellata. They are parasitic in the blood of vertebrates and cause in mammals serious diseases, such as "nagana," "surra," "dourine" in horses and "sleeping sickness" in man. The pathogenic forms are distributed

principally in South America, Asia and Africa.

Although the parasite has been known for more than half a century, very little importance was attached to it until within the last decade. As knowledge of these forms has recently advanced, so have they become very important, not only to the physician on account of their rôle in the etiology of disease, but also to the zoologist who is desirous of knowing their finer structure, their life history and their genetic affinities.

One of the important phases of the article is a discussion of the method of transmission of the parasite. Doffein points out that there are three probable modes of transmission.

The first mode is by means of cysts or spores. In such cases it would be necessary for the parasites to wander through the walls of the blood-vessels out upon the skin or mucous membrane and there form cysts. They must then be taken up with dust, water or food by an intermediate host and be carried to the vertebrate host. At present no facts are known to support this theory, except that certain authors have described stages in the blood and internal organs, which they interpreted as cysts. But these are probably nothing more than degeneration stages.

The second method is through coitus, as is the case with *Spirochæta* and the trypanosome causing dourine. Doffein is of the opinion that this mode of transmission may be possible in all trypanosomes, and hence regards it as an important point to be investigated.

The third method is the passive transmission through the agency of blood-sucking invertebrates. Experiments show that insects are capable of passively carrying the trypanosomes from an infected to a sound patient. Since the work of Schaudinn (1904) on the transformations of the owl trypanosome in the stomach of the mosquito, investigators have thought that the trypanosome must pass through a complicated life-cycle in an invertebrate host. Setting out with Schaudinn's work before them, they have tried to fit their discoveries to his interpretations. They have searched for male and female forms, believing

that there must be a life-cycle similar to malarial forms in the mosquito. But no one has ever yet seen male and female, if they exist, in process of conjugation, and so the insect is known only to be a passive carrier of the infection.

LEROY D. SWINGLE
NEBRASKA WESLEYAN UNIVERSITY,
UNIVERSITY PLACE, NEBR.

The Study of Nature. By SAMUEL CHRISTIAN SCHMUCKER. Pp. 315, illustrated. Philadelphia, J. B. Lippincott and Co. 1908. \$1.25.

This latest addition to the long list of books designed to guide teachers of nature study will, like many of its rivals, give much help; but still leaves the most pressing problems of elementary school nature study just where they were before its publication. This fact is mentioned not in criticism, but simply to forewarn those who eagerly expect each new book on nature study to make some decided advance towards complete establishment and successful teaching of the subject in all our elementary schools. For such a golden age of nature study we have as yet at most only a prophetic vision.

In the first chapters dealing with the principles of nature study the author follows the most advanced stage of the nature study movement when he urges as essential the observational study of natural things, as far as possible, in their natural relations and chosen for their commonness and abundance rather than for their rarity.

In the chapter on The Real Purpose of Nature Study the author agrees with many other writers in urging nature study as for many individuals a valuable addition to the general culture which is valuable for avocation rather than for the main business of life. Also he believes in practise in accurate observing and stating results as decidedly effective in establishing firm character, and in nature study as a guide to a religious attitude towards nature. All this agrees with the experience of many naturalists, but the doubting educators who have had no experience in scientific study will continue to regard these purposes as vague and not convincing. The

present uncertainties as to the place of nature study in our educational system are to no small extent due to the emphasis on such vague purposes which appeal to few who have not the naturalist's outlook to nature.

Most of the book is devoted to the practical problems of class-room management, materials and arrangement of the course of study. All these chapters are good introductions for the beginner, and especially for students in normal schools. Nine of the ten chapters on materials are devoted to animals and plants, and the tenth deals with popular astronomy. Just why the author has chosen the heavens as the only representative of the physical side of nature is not apparent to the reviewer. The signs of the times indicate that here is a weakness, and that the nature study which may win a permanent place in our elementary education of the future must have a well-balanced mixture of the biological and the physical. The physical is extremely important for interpreting the biological aspects of nature, and to most people it makes a more convincing appeal from the standpoint of every-day life.

The outline of a course in nature study is based on no apparent underlying principles, but like most other outlines published is simply a list of topics taken at random. All principles of continuity, correlation and logical development seem to be neglected. Of course there are those naturalists who urge that nature study should be free from everything resembling the formal work common to the school room; but that kind of nature study has decided limitations and has made little permanent progress in American schools.

Experimental Elasticity, a Manual for the Laboratory. By G. F. C. SEARLE. 8vo, pp. 187. Cambridge University Press. 1908.

The character of this book can be best seen from its origin. The author has been since 1890 director of the classes in practical physics of the Cavendish Laboratory, and has prepared for his students manuscript notes giving

the theory and description of the experiments. He is now collecting these notes, and after re-writing and amplifying them when needed, they are to be published in a series of volumes which will cover the usual field of practical physics. It is appropriate that the first volume should be on experimental elasticity, a subject in which Mr. Searle's contributions are well known.

The volume is divided into three chapters, the first two chapters being theoretical and the third chapter giving detailed descriptions of the methods and apparatus of fourteen experiments in elasticity. The theoretical parts are generally elementary, but the use of calculus methods is not avoided. The theorems and methods of thermodynamics are also used. The sections using these more advanced methods could, however, be easily omitted without interfering with the use of the greater part of the book. The "notes" forming an appendix to the above three chapters give discussions of some of the elementary theorems of mechanics and mensuration. From this we can infer that the more advanced sections may have been added later to make the book more complete. The longest of these "notes" is entitled Hints on Practical Work in Physics, and gives brief, pointed directions on keeping note-books, making diagrams, methods of calculations, adding also an occasional moral hint. Thus the following might well be copied and framed for use in many laboratories:

A steady hand, a keen eye and a good command of the body are essential in accurate physical determinations; mere intellectual power avails nothing by itself. Any rule of life which deviates from temperance in all things (including work) may be expected to render the hand less steady and the eye less keen and so lead to inferior work. University students whose fingers are deeply stained with tobacco do not, as a rule, become skilful observers, though they may show considerable ability in other ways.

Laboratory courses can not in general be transplanted as a whole, since each laboratory has its own selections of apparatus and experiments—that is, if it is a live laboratory. In the case of elasticity, the variations in forms of apparatus are not great and not funda-

mental. Hence this book will be available, particularly as a reference book, in many laboratories. The discussion of elementary elastic theory is excellent and not beyond the average undergraduate. More time is evidently given to elasticity by Mr. Searle's students than is usually possible in American colleges and universities for this part of physics. The only criticism that might be made is that several of the experiments given are very complicated for a practical physics course, but these are added experiments so that none of the standard experiments have been crowded out.

A. P. CARMAN

SPECIAL ARTICLES

A NEW GENUS OF CARNIVORES FROM THE MIOCENE OF WESTERN NEBRASKA

WHILE engaged in restudying the material described as *Amphicyon superbus* by the writer in the *Annals of the Carnegie Museum*, Vol. IV., p. 51, it has become apparent that the species, though allied to the European forms, should be regarded as generically distinct from them, and that it is more nearly related to *Daphænus* from the Oligocene of North America. The type specimen consists of a practically complete skeleton, which has been freed from the matrix and is ready for mounting. It is now being restudied and described in detail by the present writer.

For this new genus from the Miocene formation of western Nebraska I propose the name *Daphænodon*. The dentition and cranium show close similarity to *Daphænus* from the Oligocene, and the latter genus apparently represents the ancestral stock from which the proposed genus *Daphænodon* is descended.

DAPHÆNODON, gen. nov.

(Type *Daphænodon superbus* (Peterson), Specimen No. 1589, Car. Mus. Catalog Vert. Foss.)

Principal Generic Characters: Cranium comparatively short, broad, and low; muzzle large, sagittal crest prominent; brain-case small; incisors heavy and short; canines comparatively small and oval in cross-section; P⁴

with antero-internal cusp of moderately large size; M¹ and M² large and broad; M³ present, though small, practically one-rooted and aligned with the internal border of M¹ and M².

Upon very careful comparison of the type specimen of *Daphænodon superbus* with casts of *Amphicyon giganteus* (A. major Blainville) and also with illustrations of the best known European forms¹ it is evident that there are characters of considerable importance, which may be regarded as of generic value. The more important differences may be stated as follows:

The skull of *Amphicyon giganteus* is represented only by the left maxillary, but it indicates a cranium having considerably greater elevation from the alveolar border of the maxillary to the nasals than is the case in *Daphænodon superbus*. It is also seen that the alveolar border is more strongly developed posteriorly in the European genus, M¹ being succeeded by a considerable process of the maxillary, while in the American genus the border back of M¹ is extremely thin.

In the European form, *A. giganteus*, the canine is of very large size, sharply pointed, has a decided cutting edge posteriorly and a prominent rib on the antero-internal angle, which causes the cross-section of the tooth to be very elliptical, as in certain cats of the Oligocene, while the corresponding tooth in *Daphænodon superbus* is proportionally much smaller, the edges not so sharp in front and behind, and the tooth consequently having a more oval cross-section. The superior premolars in the European genus are proportionally smaller, P⁴ has a distinctly smaller antero-internal tubercle and the long axis of the crown is more nearly antero-posterior, the tooth being placed less obliquely in the jaw than is the case in *Daphænodon superbus*. The superior molars of the latter genus differ in some important particulars, viz.: M¹ is of relatively greater transverse diameter and the posterior intermediate tubercles, especially the one on M², which closes the posterior opening of the median pit in *Amphicyon giganteus*, are absent. M³ of the latter genus

¹ Blainville, Vol. II., Pl. XIV.; Filhol, *Ann. Soc. Geol.*, X., pp. 77-79, Pl. 10-16, 1879.

is of greater functional importance than the corresponding tooth in the American form.

From the illustrations of *Amphicyon lemanensis* by Filhol¹ it is seen that the occipital condyles of that form are less sessile, the mastoid process is of larger size, and the tympanic bullæ were probably smaller. It is also seen (Pl. XI, figs. 4, 6-8) that M¹ has three roots and the crown is occupied by three distinct cusps, a distinctly more conservative character, and properly to be considered as more primitive than that of the reduced and comparatively simple crowned M¹ of *Daphanodon superbis*. Another character which seems to indicate less specialization in the European genus is the short antero-posterior diameter of M₁, when compared with that of *Daphanodon superbis*.

It is further seen on comparison that the skull of *Daphanodon superbis* is less elongated than that of *Daphænus felinus* from the American Oligocene. The base of the skull back of the pterygoids is especially shortened. The muzzle is heavier. The incisors are larger, the antero-internal tubercle of P⁴ (carnassial) is less developed, M¹ and M² are more developed internally, and the postero-internal angles of M₁ and M₂ are more prominent. The position of P⁴ is less oblique in the alveolar border than is the case with the corresponding tooth in *Daphænus felinus*, a character tending toward conditions found in the recent dogs.

The limbs of *Daphanodon superbis* are comparatively long and slender, the thoracic region rather light, and the tail is very long. These are characteristic structural features of *Daphænus felinus* described by Mr. Hatcher in the *Memoirs of the Carnegie Museum*, Vol. I., pp. 66-95.

O. A. PETERSON

CARNEGIE MUSEUM,
March 20, 1909

NOTES ON MUSHROOM SPORES

In making experiments to determine if the spores of dung-inhabiting mucors pass through the stomach and intestines of animals before they germinate, an interesting fact

¹L. c., Pl. XIII., Fig. 5.

about the spores of mushrooms was discovered.

Some fresh horse manure, immediately after it was voided, was placed upon a sterilized plate and covered with a sterilized glass cover. On examining parts of this manure for mucor spores, there were found spores resembling mushroom spores. The plate was then set aside for three weeks when an abundant crop of mushrooms appeared. Examination proved them to be *Coprinus ephemerus* Fries.

There is a possibility that the spores might have been floating in the air and might have fallen upon the manure in the short time that it was exposed in the stable but it is not very probable that such was the case.

It seems practically demonstrated that these spores passed through the digestive tract of the horse and escaped any injurious effect from the process of digestion. They germinated and developed into mature plants in a very short time.

TANKS FOR SOIL INVESTIGATION AT CORNELL UNIVERSITY

THERE are certain experiments involving fundamental problems in soil productiveness that can be conducted only where it is possible to accurately measure the conditions as they exist in the field, and to maintain the records through a great number of years. Some of these problems are as follows:

Effects of the continuous use of large amounts of mineral fertilizers upon the physical and chemical properties of the soil, and upon the bacterial flora and bacterial activity.

Changes that occur in a series of years when soils gradually deteriorate or improve.

Effect of different methods of soil treatment upon the loss of lime in the drainage water.

The loss of potassium and other substances occasioned by manuring with lime.

Loss of soluble salts caused by clean cultivation.

Extent to which soils under field conditions

TANKS FOR
SOIL INVESTIGATION
CORNELL UNIVERSITY
Scale $\frac{1}{4}" = 1'-0"$

are renewed by accession of lower soil to the plowed portion.

For the purpose of conducting investigations of this kind there have been built on the farm at Cornell University a number of large tanks in which soil may be kept at the same surface level, and under conditions nearly identical with that of the surrounding soil, upon which duplicate tests are made. They are intended to furnish receptacles for bodies of soil of sufficient size to produce plants in a normal manner under approximately field conditions, and yet afford opportunity for measuring a large number of the factors affecting plant growth. The construction is of concrete, but the tanks will be lined.

Each tank is four feet two inches square with a maximum vertical depth of four feet six inches and a minimum depth of four feet. There are twenty-four tanks placed in two rows of twelve tanks each. Between the rows of tanks is a tunnel, the bottom of which is ten feet below the top of the tanks. The tunnel is six feet wide. From the lowest point in each tank is an outlet tube two inches in diameter and tin lined. It is made large enough to permit of easy cleaning and has no bends in it. A piston runs through the tube to within four inches of the upper end. Between the perforated head of the piston and the soil, glass wool is to be inserted. The piston can be withdrawn if it is desired to clean the tube.

Drainage water from each tank will be caught in a receptacle in the tunnel. The lining in the tanks will prevent any soluble material in the concrete from appearing in the drainage water. A constant water table at any desired depth may be maintained by raising the rubber tube leading from the outlet tube to a corresponding point below the surface of the soil in the tank.

The tanks, as described, will each contain between three and four tons of soil, and the surface will constitute approximately .0004 of an acre. They are built with special reference to durability so that it will be possible to plan for experiments to extend over a long period. The quantity of soil contained is not

too large to allow of accuracy in sampling and yet is sufficiently large to closely resemble field conditions, which is not true of the quantity contained in pots. No covering is to be placed over the tanks, but in every way natural conditions are to be permitted. The top soil and subsoil will be placed in their relative positions. It is expected that the rainfall will be sufficient to meet the needs of the crops, but if the plants suffer during periods of drought they can be watered artificially.

Any desired type of soil may be used which is not possible with ordinary field experiments. It is also possible to make a comparison of different soil types under any desired condition which may be very serviceable in ascertaining the effect of those properties differentiating these types upon certain factors in soil productiveness.

The chief feature of the plan is that of keeping accurate records of the factors affecting plant growth without producing artificial conditions.

The tube leading from the bottom of the tank is designed to carry off the drainage water into a receptacle which will permit the quantity to be measured and its constituents to be determined.

The accompanying diagram shows the plan and cross-section of these tanks.

T. L. LYON

THE GEOLOGICAL SOCIETY OF AMERICA

THE twenty-first annual meeting of the Geological Society of America was held under the presidency of Professor Samuel Calvin, of Iowa City, Iowa, in the rooms of the geological department, Johns Hopkins University, Baltimore, Tuesday, Wednesday and Thursday, December 29, 30 and 31, 1908.

The first session of the meeting was called to order at ten o'clock Tuesday morning with President Calvin in the chair and the society was cordially welcomed to Baltimore by Professor W. B. Clark in a few well-chosen remarks, to which appropriate response was made by President Calvin.

The secretary, Dr. E. O. Hovey, of the American Museum of Natural History, reported that the printed list of fellows contained 294 names, the

same as at the time of making the last annual report. During the year the four new fellows elected at the Albuquerque meeting qualified; two fellows, Homer T. Fuller and William S. Yeates, were lost by death, and two by resignation. After presentation of the memorials of the deceased fellows the regular program of papers was taken up as follows:

The first paper read was:

Some Distinctions between Marine and Terrestrial Conglomerates: JOSEPH BARRELL, New Haven, Conn.

The problem was approached by studying the effects of shore, as compared with subaerial, activities upon the production, transportation and deposition of gravel. It has been found that the truly terrestrial forces produce vastly more gravel, spread it far more widely, and provide more opportunities for deposition, than do the forces of the littoral zone. Conglomerate formations, therefore, should be dominantly of terrestrial origin. In order to determine, however, the mode of origin of particular examples, definite criteria must be drawn between the two classes. It was shown that the thickness was one of the most important of these marine conglomerates, except under local and special circumstances, being limited to considerably less than one hundred feet in thickness, terrestrial conglomerates, on the other hand, being frequently measured in hundreds and occasionally in thousands of feet.

Attention was next turned to the significance of the intercalated non-conglomeratic beds and the relations to the under- and over-lying formations, with the conclusion that the characteristics of the associated strata are frequently of high supplemental value for determining the mode of origin.

Applications of the conclusions were made to several conglomeratic formations.

Professor Barrell's paper was discussed by Messrs. G. K. Gilbert, J. Barrell and W. H. Hobbs.

The following papers were read by title:

The Chemistry of the Pre-Cambrian Rivers: REGINALD A. DALY, Boston, Mass.

The Primary Origin of the Foliated Structure of the Laurentian Gneisses: FRANK D. ADAMS and ALFRED E. BARLOW, Montreal, Canada.

Relations of Present Profiles and Geologic Structure in the Desert Ranges: CHARLES R. KETES, Des Moines, Iowa.

Deflation and the Relative Efficiencies of Erosive Processes under Conditions of Aridity: CHARLES R. KETES, Des Moines, Iowa.

Then were read:

Unconformity Separating the Coal-bearing Rocks in the Raton Field, New Mexico: WILLIS THOMAS LEE, Washington, D. C.

The coal-bearing rocks of northern New Mexico in the vicinity of Raton occupy the southern part of the Raton Mountain region. The rock formations are the same as those of the Trinidad coal field in southern Colorado, heretofore referred to the Laramie. Recent work in the Raton field has proved that there are two coal-bearing formations separated in time by a period of erosion. The evidence of the hiatus is found: (1) in the partial removal of the older beds, (2) in the character of the pebbles found at the base of the younger formation, (3) in the affinities of the fossil plants.

Evidence that the Appalachian and Central Coal Fields were once connected across Central Kentucky: ARTHUR MILLER, Lexington, Ky.

In support of the view long entertained, that the different Carboniferous coal fields of the United States were formerly connected, the writer during the past summer found deposits of Coal Measure conglomerate in a narrow band along the watershed between the Green and Salt rivers, and in previous years had noted it between Bacon Creek, a tributary of Nolin River, and Green River; and also on the top of King's Mountain, near the head of Green River. During most of this stretch it forms the crest of Muldrow's Hill. It consists of massive boulders of large quartz pebble conglomerate and great banks of pebble and sand waste. It has contributed much material to the lands lying south of Muldrow's Hill, giving to many of them a sandy character. It itself, near the middle of its course, is deeply dissected, resembling in its topography, soils and population, the same formation in eastern Kentucky.

The Bearing of the Tertiary Mountain Belt upon the Origin of the Earth's Plan: FRANK BURNLEY TAYLOR, Fort Wayne, Ind.

Suess showed with great clearness and force that the peripheral mountain system of Asia was formed by horizontal thrust movements from the north; i. e., from the interior of the continent towards the ocean.

In the present paper the following points are dwelt upon as tending to confirm Suess's generalization and the writer's extension thereof:

1. The Tertiary mountain arcs and island festoons of Asia bulge outward towards the south, showing southward crustal creep of the continental mass.

2. The Himalaya mountain range exceeds others in height, because it was so severely pressed against the north side of the older plateau of

India. The Malay arc, lapping around the eastern end of the Himalaya and swinging far to the south—even beyond the equator—met no such obstacle. It spent itself more freely and formed the most remarkable of the great earth-lobes of Asia.

3. At its eastern end the tectonic line of the Aleutian island arc penetrates to the heart of the mountain knot of Alaska, so that westward from about the 148th meridian, west longitude, Alaska belongs structurally to Asia.

4. The Tuscarora deep, close in front of the Japan and Kurile Island arcs, and also the long, narrow deep, close in front of the Aleutian arc, mark areas probably in part elastically depressed by the weight of the adjacent more or less overthrust masses. They mark the negative side of these great tectonic lines, while the high, though largely submerged, mountain ranges of the adjacent island arcs mark the positive, uplifted side of the same lines. These troughs are now unfilled, because the uplifted ranges near them have remained largely submerged and hence have supplied little or no sediment.

5. The mountain knot of Alaska was raised to its extraordinary height by a convergence of crustal creeping movements. It is precisely in the angle where the southeastward creep of the Aleutian earth-lobe came into conflict with the south-westward creep of northern North America.

6. The peculiar rift valleys on the northern and western sides of Greenland suggest a rending and tearing away of Grant Land, Baffin Land and Labrador from Greenland, due apparently to crustal creep towards the south and southwest, Greenland remaining as the great northern horst. The import of these several facts added together is Tertiary southward crustal creep, with peripheral faulting, folding and uplifting for all the northern continents.

7. Australia's Tertiary peripheral mountain belt lies in island chains seaward from its northern and eastern coasts, indicating northward and eastward crustal creep. South America's belt is on its northern and western sides, indicating northward and westward creep. Thus, the two southern continents show in general northward creep, but with a considerable amount of deflection.

8. The Celebes and Malmahera islands show remarkable "chiragratie" mountain plans, and they are precisely in the zone of conflict between the southward crustal creep of Asia and the northward crustal creep of Australia. Borneo is in the same zone and has a similar mountain plan.

Conclusions.—The foregoing facts show crustal

creep in both hemispheres from high towards low latitudes. This is not explicable by any form of contraction hypothesis, but is the normal result of a force tending to deform the lithosphere by slightly and permanently increasing its oblateness—the same in effect as if the earth's axial rotation had been slightly and permanently increased. No contraction hypothesis can account for the occurrence of this remarkable epoch of mountain making at so recent a time as the Tertiary age, unless it can provide some method of storage of mountain making forces which shall endure and continue to accumulate through several geologic ages, with occasional mountain making in moderate degree going on at the same time.

The action of such a force would cause a depression of both polar areas, resulting in crustal creep towards lower latitudes. Inevitably, one polar area would yield before the other or else in greater amount. The pole from which the first large shift of mass took place would ever after take the lead and be the more active area in crustal movement, for that first movement would slightly displace the earth's center of gravity, moving it towards the other pole, where the shift of mass was less, and this change itself would intensify the deforming forces at the first pole and diminish them at the other. Thus, the first pole, corresponding to the north pole of the earth, would progressively emerge from the sea, would suffer the greater deformation and would therefore have an excess of land or continental areas around it, while the other (south) pole would be progressively submerged, would suffer less deformation and would have a minimum of land or continental areas around it. This may explain why the north pole is girdled by land and the south pole by water.

The forces causing southward crustal creep in the northern hemisphere were strongest in high northern latitudes and diminished towards the south; and further, the area of earth-crust upon which the forces acted increased towards the south. Perhaps these two conditions, modified by the tendency to a limited number of meridional rifts due to girth expansion in the equatorial belt, explain the triangular shape of the continents—broad at the north, where a land belt almost girdles the earth, and tapering in sharp points towards the south.

Mr. Taylor's paper was discussed by Professors H. F. Reid, B. K. Emerson, J. Barrell, W. H. Hobbs, A. P. Coleman and F. B. Taylor.

The session then adjourned at 12:30 P.M.

The society convened again in two sections at

2:10 P.M. The first paper presented in the main section, under the chairmanship of President Calvin, was:

On Faults: HARRY FIELDING REID, Baltimore, Md.

This was followed by

Mass Movements in Tectonic Earthquakes: HARRY FIELDING REID, Baltimore, Md.

These papers were discussed by Professor W. H. Hobbs and H. F. Reid.

The next paper was read by title:

The Alaskan Earthquake of 1899: LAWRENCE MARTIN, Madison, Wis. (Introduced by C. K. Leith.)

The society then listened to

A Recent Landslide in a Shale Bank near Cleveland accompanied by Buckling: FRANK R. VAN HORN, Cleveland, Ohio.

The landslide in question took place at the plant of the Cleveland Brick and Clay Company, beginning Monday, August 17, 1908, at 3 P.M., and lasting until late the following day. The shale bank is about 112 feet high and consists of about 3 feet of drift, 21 feet of Cleveland shale and 88 feet of Erie Chaghn shale of the uppermost Devonian. The bank cracked along the valley for a length of 250 feet and followed weathered joint planes almost entirely. The width of the crevice varies up to 22 feet and the vertical displacement is 6 to 7 feet. The mass broken off has been estimated variously up to a million tons, but one hundred thousand tons is probably excessive. After the crevice reached its widest dimensions, the severed block settled back towards the cliff about 1 foot, producing a noticeable dip of the shale layers, at the same time the valley floor at the base of the cliff buckled up into an anticline 4 to 5 feet in the highest portion and traceable over a distance 200 feet. The buckling continued over a period of two months after the crack formed. Buckling is quite often noticed in shales along the edges of stream valleys and it is possible that such movements have been caused by similar landslides.

This paper was discussed by Professors H. P. Cushing, J. W. Spencer, G. B. Richardson, F. R. Van Horn, G. K. Gilbert and G. H. Ashley.

Then was read by title:

The Volcano Kilauea: C. H. HITCHCOCK, Honolulu, Hawaiian Islands.

After this was presented:

Mt. Pelé of Martinique and the Soufrière of St. Vincent in May and June, 1908: EDMUND OTIS HOVEY, New York, N. Y.

The paper gave the results of an expedition made to the Lesser Antilles in April to July, 1908, illustrating by means of lantern slides the progressive changes in 1902, 1903 and 1908 due to the great eruptions and the efforts of nature and man to recover from them.

The last paper of the afternoon was:

Multiple Glaciation in New York: H. L. FAIRCHILD, Rochester, N. Y.

Evidence of pre-Wisconsin glaciation in territory surrounding New York State—in Canada, Ohio, Pennsylvania, New Jersey and New England, implies a similar history for the state.

An accumulating body of fact points to at least two ice invasions. Such features are: (1) the widespread occurrence of more or less difference between the surficial and the deeper till; as shown in color, texture, composition, with sometimes a distinct surface of separation; (2) weathered glaciated surfaces and heavy glacial flutings merely scraped in places by a later abrasion; (3) old planation surfaces which though protected by Wisconsin till have lost their glaciated character; (4) probable stream channels not the product of the latest glacial drainage; (5) physiographic features of anomalous relationship.

No interglacial deposits have as yet been found.

This paper was discussed by Professor G. K. Gilbert, R. S. Tarr, F. Carney, A. Penck and A. P. Brigham.

Adjourned at 5:25 o'clock.

The society met at 8 o'clock Tuesday evening in the lecture room of the geological department to listen to the presidential address of Professor Samuel Calvin, who chose as his theme "The Latest Phase of the Pleistocene Problem in Iowa." This paper will be published in full in *SCIENCE*.

At the close of the address, the society and its friends adjourned to the rooms above the lecture hall and participated in a "smoker" as the guests of the geological department of the university, the function closing shortly before midnight.

Wednesday morning the society came to order in general session, President Calvin presiding, at 9:35 o'clock, and after the consideration of some matters of business listened to the reading of a letter from Hon. Gifford Pinchot, chairman of the National Conservation Commission, requesting the appointment of a committee by the Geological Society of America with which the commission might confer regarding geological subjects. It was voted to empower the president to appoint three fellows to act as a committee on conservation.

Then was presented a paper by Professor Albrecht Penck, of Berlin, who had been invited by the council to participate in the meeting. Professor Penck chose as his theme "Interglacial Epochs."

At the close of this paper the special section on correlation withdrew for the continuation of its sessions, and the general section, with President Calvin in the chair, proceeded with the main program.

The following two papers were read:

Glacial Waters West and South of the Adirondacks: H. L. FAIRCHILD, Rochester, N. Y.

As the lobes of the ice sheet melted away south of the Adirondacks, high-level waters were held in the Schoharie and Mohawk valleys, into which was poured the land and glacial drainage of the time, with consequent elevated deltas. The Schoharie Lake had outlets to the Hudson and the Delaware; and subsequently the Mohawk waters overflowed southwestward to the Susquehanna, but finally to the Hudson.

The earliest outlet of the Mohawk Valley waters seems to have been by the col at the head of the Otsego-Susquehanna valley, with elevation somewhat under 1,400 feet. A lower escape was found by the Unadilla Valley, at about 1,220 feet, and possibly by the Chenango Valley at 1,150 feet. Later the outflow was eastward to the Hudson by Delanson and Altamont and past the face of the Helderberg scarp, at 840 feet as the lowest. The latest flow of the ice-impounded Mohawk waters was south of Amsterdam and past the face of the scarp at Rotterdam.

The copious drainage of the western slopes of the Adirondacks poured into a lake held in the valley of Black River, with the production of a remarkable expanse of sand plains. In the various features and relations which characterize a glacial lake the Black Lake is probably the finest example of a glacial lake in the state (though not nearly so remarkable in complexity of drainage and history as the Genesee waters). The earliest outflow of the differentiated waters of the Black Valley was southward past Remsen into the Mohawk Lake, with delta built at Trenton and Trenton Falls. The second escape was southwestward, at Boonville, into the inferior Mohawk Lake, with delta north of Rome. The third stage had westward outflow, curving around the high ground between the Black Valley and the Ontario basin, at Copenhagen and Champion, the flood pouring into Lake Iroquois at Adams.

Correlation of the Hudsonian and the Ontarian Glacier Lobes: H. L. FAIRCHILD, Rochester, N. Y.

In the waning of the Labradorian ice body the Adirondack massif became uncovered, at first as an island, with probable westward flow of the ice through the Mohawk depression. Later the glacial flow was divided into a Champlain-Hudson lobe and a St. Lawrence-Ontario lobe. For a long time the Hudsonian lobe pushed an ice tongue westward into the lower Mohawk valley, while the Ontarian lobe sent one eastward into the upper Mohawk valley. Imprisoned between the two opposing ice fronts the glacial waters stood at high levels in the Mohawk and Schoharie valleys. As the waning ice margins released successively lower passes to southern drainage the waters fell accordingly.

The delta sand plains on the flanks of the Adirondacks and in the upper Mohawk valley, with their various declining altitudes, show the successive levels of the waters; and these levels were determined by the positions of the ice margins with reference to a few critical cols or passes on the divide.

These two papers were discussed by Professors A. P. Brigham, H. L. Fairchild and A. W. Grabau.

The next paper was read by title. It was:

Pleistocene Features in Northern New York: H. L. FAIRCHILD, Rochester, N. Y.

Then the society listened to:

Pleistocene Geology of the Southwestern Slope of the Adirondacks: W. J. MILLER, Clinton, N. Y. (Introduced by W. B. Clark.)

The area discussed in the paper is about sixty miles long and fifteen miles wide and extends from Lowville to Dolgeville, N. Y. Certain evidence clearly indicates an early southeasterly movement of the ice, while other evidence shows a later, more general southwesterly direction of flows. The Black River Valley has been considerably deepened and modified by ice erosion. A distinct kame-morainic belt has been traced the whole length of the area. Associated with this moraine are so-called "sand plains," whose origin is discussed. Extinct glacial lakes are shown by the presence of considerable areas of stratified clay. The pre- and post-glacial drainage of the region and the origin of the "gulfs" were discussed.

The paper was discussed by Professor G. K. Gilbert.

Then was read:

Weathering and Erosion as Time Measures:
FRANK LEVERETT, Ann Arbor, Michigan.

The paper aimed to set forth the use that may be made of weathering and erosion in determining relative age of the several drift sheets. It also dealt with the most important qualifying conditions that affect estimates.

At the close of the reading of this paper, at 12:30 o'clock, adjournment was taken, discussion being postponed to the afternoon.

The society convened again at 2 o'clock, President Calvin presiding, and took up the discussion of Mr. Leverett's paper, the participants being Professors A. Penck, S. Calvin, F. Leverett, G. F. Wright and G. K. Gilbert.

The next two papers were then read:

The Glacial Phenomena of Southeastern Wisconsin: WM. C. ALDEN, Washington, D. C. (Introduced by T. C. Chamberlin.)

A graphic presentation by a map 9×10 feet, scale one mile per inch, of a detailed study of the deposits of the Green Bay and Lake Michigan glaciers and associated phenomena of late Wisconsin glaciation of southeastern Wisconsin. The map covers an area approximately 8,600 square miles, which has been under study by the author under the direction of Dr. T. C. Chamberlin, during the greater part of the last ten years. The presentation comprised such description as the time permitted of the conditions affecting the advance of the two glaciers, their relations to each other, the character, distribution and mode of formation of the several deposits, terminal and recessional moraines, outwash deposits, ground moraines, drumlins and eskers, the lithological composition of the drift and its significance. Evidence was presented by a deposit of red till of a later readvance of the two glaciers southward to the vicinities of Milwaukee and Fond du Lac. The shore lines and deposits of Lake Chicago and succeeding glacial lakes were also shown.

Concerning certain Criteria for Discrimination of the Age of Glacial Drift Sheets as Modified by Topographic Situation and Drainage Relations: WM. C. ALDEN, Washington, D. C. (Introduced by T. C. Chamberlin.)

The discussion was confined to phases illustrated by the pre-Wisconsin drift of southern Wisconsin and northern Illinois.

Character of this drift and reasons for regarding the drift exposed at the surface throughout this area as belonging to one and the same sheet. The lithological composition and its significance,

directions of ice movement, absence of intercalated weathered zones, soils or vegetable deposits.

Differences in the apparent amount of surface modification of this drift in different parts of the area which might be regarded as indicating differences in age:

1. Topographic relations and amount of erosion.
2. Weathering, leaching and oxidation. The occurrence in places of thoroughly disintegrated drift or residual till; in others, of drift but moderately leached and oxidized; in others, of perfectly fresh unmodified drift at the surface or immediately below the loess.

The reasons for these differences:

1. Influence of pre-Glacial topography on drainage slope and upland of the drift. Influence of the St. Peter sandstone on the pre-Glacial topography. Relations of surface wash to the apparent amount of surficial leaching and oxidation.
2. The post-Illinoian diversion of Rock River below Rockford, Illinois, and the consequent retardation of erosion due to the work of cutting new rock gorges at several cols. Removal of the weathered drift from slopes with preservation on the uplands.

Necessity for caution in the discrimination of distant drift sheets in the absence of marked differences in lithological composition or of sections showing overlapping drift with intercalated soils, vegetable deposits or weathered zones.

The two papers together were discussed by F. Leverett.

Then was read:

Lake Ojibwa, the Last of the Great Glacial Lakes:
A. P. COLEMAN, Toronto, Canada.

As the Labrador ice sheet retreated north to the watershed between the Great Lakes and James Bay, the waters now flowing northward were impounded, first as a narrow bay of Lake Algonquin opening south past Sudbury, afterwards as a separate lake with an outlet down the Ottawa Valley. This lake probably existed during the time of the Nipissing Great Lakes, and was the last of the ice-dammed lakes. The elevation of its outlet is now 900 feet, but was then much lower. In its bed the "clay belt" of northern Ontario and Quebec was deposited, having an extent of over 25,000 square miles. The maximum area covered by its waters must have been greater than that of Lake Superior; though probably its extent varied greatly in accordance with the position of the ice front.

This paper was discussed by Mr. F. B. Taylor and Professor A. P. Coleman.

The next paper was:

Glacial Erosion on Kelley's Island, Ohio: FRANK CARNLEY, Granville, O.

Last summer a rectangular area about 100 rods long and 4 rods wide was stripped to open a new quarry. This area is transverse to the direction of ice-motion; its southern part does not show the slightest evidence of rasping by stone-shod ice. This rough unglaciated surface ends abruptly in a perfectly smooth, scored area which continues about 800 feet, where it again borders limestone bearing no marks whatever of ice-work. The erosion features thus revealed are so in contrast with the long-known glaciated surfaces near by that the case deserves special consideration.

The paper was discussed by Professor G. F. Wright.

Then was read:

The Chalk Formations of Northeast Texas: O. H. GORDON, Knoxville, Tennessee.

Extending in a west to east direction across the southern part of Lamar County and thence northeast through Red River County to Red River and having a width of from one to three miles, is a belt of chalk known as the Annona chalk from the town in Red River County near which it outcrops. In the earlier publications relating to the Cretaceous of Texas, this formation was considered as the diminished representative of the Austin chalk of central Texas. Later authors, however, have contended that it represents a higher horizon and belongs within the so-called Navarro division of the Upper Cretaceous.

Recent investigations by the author, in connection with the study of the underground waters of northeastern Texas, tend to confirm the earlier view as advanced by Taff that the Annona is the northeastward extension of the Austin formation. Tracing the outcrop of the Annona westward it was found to merge with that of the Austin as exposed in the vicinity of Honey Grove and westward to Sherman. At Austin the formation has a reported thickness of about six hundred feet and is composed essentially of chalk throughout. Toward the northeast the lower beds become marly, the thickness of the chalk marl increasing until in the vicinity of Red River the marls have a thickness of about four hundred feet. To this part of the formation, as represented in northeastern Texas and southwestern Arkansas, Hill applied the name Brownstown beds.

The relations seem to indicate that at the beginning of the Austin epoch the conditions for the formation of pure chalk existed only in the region about Austin, but with the progress of

time they were extended farther and farther northeast as a result possibly of a change in the relative position of land and sea.

The next paper was read by title:

Geologic History of the Ouachita Region: E. O. ULRICH, Washington, D. C.

After which was read:

Some Results of an Investigation of the Coastal Plain Formations of the Area between Massachusetts and North Carolina: WM. BULLOCK CLARK, Baltimore, Md.

The author has under his supervision for the U. S. Geological Survey the investigation and correlation of the coastal plain formations occupying the territory between Massachusetts and North Carolina, inclusive, and has had associated with him in his work a number of co-workers. Some preliminary results of significance have been secured and the formations already studied in detail in New Jersey, Delaware and Maryland have been traced beyond the borders of those regions. The extension of certain of these formations southward through Virginia and North Carolina and the recognition of new members of the coastal plain series have materially added to our knowledge of coastal plain geology. Some of the more significant results of this work were presented.

This paper was followed by the reading of:

The Geologic Relations of the Cretaceous Floras of Virginia and North Carolina: EDWARD W. BERRY, Baltimore, Md. (Introduced by Wm. B. Clark.)

The evidence of the fossil plants concerning the geologic segregation and correlation of the Cretaceous of the Middle Atlantic Slope was presented by the author. Floras similar to those of the adjoining region to the northward have been found at many localities, indicating the extension to the southward of a number of the formations.

The special section on correlation having adjourned, the society then listened in general session to the following papers:

Paleogeography of North America: CHARLES SCHUCHERT, New Haven, Conn.

The ancient geography of North America, beginning with the Cambrian, was discussed and illustrated by from forty to fifty maps of as many different times. These maps give the probable extent of the marine inundations over the North American continent, and show the extent of the faunal provinces.

The diastrophism indicated by these maps is plotted on a time-geographic curve to show the

extent and duration of the periodic submergences and emergences.

The paper was discussed by Mr. B. Willis.

Revision of the Paleozoic Systems in North America: E. O. ULICH, Washington, D. C.

Following a brief statement of current and earlier classifications of the Paleozoic rocks and of the evidence, almost solely paleontologic, upon which the present classification is founded, a new grouping of the formations was suggested. The proposed classification is based primarily on crustal movements, diastrophism, the succession of which is determined by the faunal evidence. The occurrence of such movements is determined, aside from plain physical evidence, primarily by mutations in the faunas, especially by the introduction of new faunal elements and facies, and their relative importance by (1) the extent and direction of the submergences and emergences of land masses induced by the movements and (2) the degree of the corresponding faunal mutations. In determining the boundaries of the various kinds of units, formations, groups, series and systems, the *introduction* of the new faunal elements is insisted on as an essential factor, second in importance only to positive evidence of crustal movements, in producing a scheme of classification having the desirable features of (1) simplicity of arrangement and expression, (2) sharp definition of the major groups, (3) approximate coordination in time values of the various classes of units, (4) a high degree of accuracy in correlation of geographically separated stratigraphic units and (5) the elimination of such hybrid terms as Cambro-Ordovician and Devon-Mississippian. An attempt was made to express the extent and direction of submergences and emergences graphically by a series of curves which it is believed show an appreciable rhythm in occurrence. Considering that the evolution of the scheme involves the determination of the essential contemporaneity of many hitherto not satisfactorily related geologic events, some time was devoted to the discussion of such of the principles of correlation as have been proved by field experience to have the greatest practical value.

Among the changes proposed, the most important is a new system, the Ozarkian, comprising a number of long-misunderstood formations, typically represented in southeastern Missouri and northern Arkansas, but found also in the Appalachian Valley from New York to Alabama, in the upper Mississippi Valley, in Oklahoma, central Texas and elsewhere. Both the upper and lower

boundaries of the Ozarkian are defined by more or less marked unconformities. Often the base is in contact with Acadian Cambrian, but at other localities a series of beds or formations, commonly referred to as "upper Cambrian," intervenes.

The top is succeeded by one or another of a great range of formations. In the most complete sections the next strata are of Beekmantown age, in others, however, the succeeding bed is much younger. Concerning the fauna of the Ozarkian, it is to be said that the trilobites and brachiopods, though all new, remind one strongly of preceding Cambrian types. The other classes, among them a host of gastropods and cephalopods, are quite different and on the whole closely allied to Ordovician genera and species.

Suggested changes of comparatively minor import were (1) the correlation of the Richmond with the Medina and, hence, the removal of that group to the Silurian; (2) the restriction of the Devonian to the lower and middle Devonian of current classifications and the transfer of the upper Devonian to the next younger system; finally (3) it was argued that the Meramec and Chester groups of the present Mississippian constitute another system coordinate in value to the Silurian and Devonian.

Mr. Ulrich's paper was interrupted by adjournment at 5:45 P.M. and the reading was finished on Thursday. It was discussed by Professor A. W. Grabau.

At 7 o'clock Wednesday evening the fellows and their friends, to the number of 133, gathered at the Hotel Rennert and sat down together at the annual dinner of the society. President Calvin presided, and, after dinner, remarks were made by him and Messrs. Gilbert, Penck, W. B. Clark, G. O. Smith, Brock, Chamberlin, Hovey, Gulliver, Van Hise, Emerson and Stevenson.

The society convened again at 9:45 o'clock Thursday morning, President Calvin being chairman, and after hearing sundry announcements by the secretary listened to the reading by the secretary of the following report from Professor T. A. Jagger, Jr., chairman of the committee on earthquake and volcano observations:

"Acknowledgments have been received from the governors of the Leeward Islands, of Hawaii, of Jamaica and of St. Thomas, from the chairman of the Isthmian Canal Commission and from the secretaries of the Smithsonian Institution and of the committee on seismology of the American Association for the Advancement of Science.

"Hon. W. F. Frear, governor of the Hawaiian Islands, writes:

"Hawaii is an important point for observations of this kind, but how much can be done in this direction is a question. I shall be glad to give what encouragement I can in this matter. The federal government now has a magnetic observatory here, which also contains a seismograph."

"Wm. Johnstone, Esq., colonial secretary of Jamaica, writes:

"In reply I am to state for the information of the society that the Weather Service of Jamaica has already in use two seismometers in this island, one at Kingston and one at Chapelton, about the center of the island, and that there are now being constructed here about a dozen seismometers on an improved principle."

"Col. Geo. W. Goethals, chairman and chief engineer of the Isthmian Canal Commission, writes:

"We have now at Ancon, Canal Zone, an observatory equipped with a complete assortment of modern, self-recording meteorological instruments, i. e., barograph, air and water thermometer, hydrograph, barograph a poid, triple register (wind direction and velocity, rainfall and sunshine) and the standard instruments necessary properly to correct their records. We expect shortly to erect two horizontal pendulum Bosch-Omori seismographs—one a hundred-kilogram pendulum instrument (tromometer), which will enable us to obtain registered records on smoked paper of all movements of a telluric nature, either seismic or otherwise, near or distant, and also the variations of the vertical line. The magnification is 100, and the period of oscillation of the tromometer can be extended to forty seconds. Attached to this instrument is an air-damping apparatus, by which the oscillations may be reduced, or even rendered aperiodical. Owing to its sensitiveness, this instrument is well adapted to the registration of earth tremors, pulsatory oscillations, and comparatively quick period earthquake vibrations."

"The proposed new equipment, therefore, will be such as to enable us to make observations in connection with earthquakes, whether of a tectonic nature, or produced by volcanic action, as well as of other physical phenomena, such as earth tremors and pulsations, which may, as premonitory signs, have a bearing on the prediction of earthquakes. We are also prepared to study the relations that may exist between seismic disturbances, pressure and temperature."

"While we can not make our studies cover the entire field of seismology, we believe our observations will be of considerable utility in the work

that the Geological Society of America has undertaken."

"The chairman of your committee has to report for his own district that, through the efforts of Professor J. B. Woodworth, Harvard University has installed a seismograph which is in active operation, and that money has been given by citizens of Boston whereby another Bosch-Omori instrument has been secured, and plans and drawings are now under consideration with a view to the building of a geophysical observatory near Boston which will be under the direction of the department of geology of the Massachusetts Institute of Technology."

The secretary reported from the council the constitution of W. B. Clark, H. E. Gregory, C. W. Hayes, J. M. Clarke and E. O. Hovey a committee to confer as to details with a committee of organization which had been chosen by certain paleontologists desiring to form a Paleontological Society as a section of and in close affiliation with the Geological Society of America, the council heartily commending the project. On motion the action of the council was endorsed and the committee given authority to act for the society.

The society then divided into two sections, as on Wednesday afternoon, and the following papers were presented under the chairmanship of President Calvin:

A Classification of Crystals based upon Seven Fundamental Types of Symmetry: CHARLES K. SWARTZ, Baltimore, Md.

A new and elementary development of the 32 groups of crystals was given, showing that all crystals fall into seven fundamental divisions based upon symmetry which are independent of the seven systems of crystals. Each of these types was characterized and a classification of crystals upon this basis was proposed. It is believed that the recognition of these divisions greatly simplifies the presentation of the subject of crystallography.

This paper was discussed by Professors W. H. Hobbs, E. H. Kraus, W. N. Rice and H. B. Patton. The following paper was presented by title:

The Use of "Ophitio" and Related Terms in Petrography: ALEXANDER N. WINCHELL, Madison, Wis.

Then was read:

Chemical Composition as a Criterion in Identifying Metamorphosed Sediments: EDSON S. BASTIN, Washington, D. C. (Introduced by G. O. Smith.)

This paper called attention to the small number of definite statements, even of a qualitative char-

acter, in geological literature, as to the nature and value of chemical criteria in distinguishing schists of sedimentary from those of igneous origin. Quantitative statements are wholly wanting.

By compiling a large number of analyses of pelitic sediments the writer showed the nature of the chemical changes involved in their metamorphism. He then proceeded to contrast the composition of the pelitic schists and gneisses with that of their allies among igneous rocks. The calculation of the "norm" of a schist and its classification according to the quantitative system of Cross, Iddings, Pirsson and Washington was pointed out as a convenient method for making such comparisons.

These statistical studies brought out not only the character of the chemical criteria which may be used, but gave a quantitative measure of their value. The paper concluded with the application of these criteria to certain selected schist and gneiss analyses.

The discussion on this paper was participated in by Professors B. K. Emerson, W. S. Bayley, F. D. Adams and E. S. Bastin.

After the following paper was read by title:

Petrology of the South Carolina Granites (Quartz Monzonites): THOMAS LEONARD WATSON, Charlottesville, Va.

The next two papers, being on related topics, were presented in succession:

Tertiary Drainage Problems of Eastern North America: AMADEUS W. GRABAU, New York City.

The Laurentian River of Spencer carried the collected drainage of the Great Lakes through Ontario Valley and out by the way of the present St. Lawrence. The Finger Lake valleys and the Genesee are regarded as made by tributary northward flowing streams. Fairchild regards these as northward-flowing tributaries of a (possibly) westward-flowing river in the Ontario Valley. The author has in the past shown that a normal sequential drainage system, the general direction of which was northward, and in which the minor streams were beheaded by the master, accounted for all the topographic features of the region in question. Subsequent blocking of some of the channels by drift and deepening of others by ice, and a general depression of the country to the northeast, has produced the present drainage system. The problems were discussed in the light of accumulated facts.

Drainage Evolution in Central New York: H. L. FAIRCHILD, Rochester, N. Y.

The paper aimed to assist in the elucidation of the complete physiography of the west half of New York State. Three maps represented graphically the general evolution of the drainage and the interference by glacier invasion of the normal stream development.

The first map showed the existing valleys which are an inheritance from the primitive (consequent) drainage, southwestward, across the uplifting coastal plain. These inherited valleys fall into three classes: (a) those in which the present flow is the same as the primitive, (b) those which are abandoned or left as "hanging" valleys and (c) those in which the stream flow has been reversed. A remarkable parallelism is exhibited by these valleys, which, except in the district of the Delaware and upper Susquehanna, are transverse to the present master streams. The primitive Susquehanna continued directly south at Lanesboro, instead of bending northwest as now, and occupied in Pennsylvania the Tunkannock Valley. Other valleys in northern Pennsylvania represent the continuation of the southwestward flow in central New York.

The second map exhibited the hypothetical Tertiary drainage. During Mesozoic and Tertiary time all the drainage of the west half of the state was diverted westward (subsequent) and northward (obsequent) into a great trunk stream that occupied the Ontario and Erie valleys and probably drained westward into the Mississippi basin. The cause of this radical reversion of flow was the great thickness of non-resistant rocks in the Ontario district. In the vertical series of strata between the Trenton and the Portage, on the Cayuga meridian, are 5,150 feet of rock of which 4,500 feet are weak shales, 350 feet limestone and 250 feet sandstone.

The pre-Glacial divide was far south in Pennsylvania. The Allegheny system poured north through the lower Cattaraugus Valley. The upper Genesee was tributary to the broad Danville-Avon River, which almost certainly had its northward course through the Irondequoit Valley. The Susquehanna turned west from the site of Lanesboro and Susquehanna villages along the strike of the Chemung strata, which were less resistant than the overlying Catskill, past the sites of Binghamton, Owego and Waverly, and then curved north through the sites of Elmira and Horseheads and occupied the Seneca Valley. The Chemung was the principal tributary from the west, as to-day, but it passed north of Elmira instead of south, where it now lies in a post-Glacial cut.

The Delaware and the upper tributaries of the

Susquehanna were not diverted from their south-west courses.

Along the Ontario lowland the Tertiary channels are almost entirely destroyed or obscured by drift, but the valleys of Irondequoit, Sodus, Little Sodus and Fairhaven are trenches across the Niagara-Medina scarp which probably represent the northward pre-Glacial flow. To-day only two large streams pass across this rock ridge, the Genesee and Oswego, both in new channels. It seems probable that along the belt of Salina outcrop the pre-Glacial tributary streams flowed east or west as they do to-day.

It was suggested that the "oversteepened" walls of the bottom sections of the Finger Lakes valleys were produced by the rapid down-cutting of the streams during the Tertiary uplift.

The third map showed the principal stream flow as compelled by the ice sheets. A few strong south-leading valleys were enlarged or newly cut by the concentrated glacial waters, and the Allegheny and Susquehanna systems were turned to the south. In order from west to east the glacially developed valleys are Cassedaga, Conewango, Iachua, Canisteo, Cohocton, Cayuta, Cattatunk, Tioughnioga. These southeastward drainage lines, transverse to the primitive flow, were carved from numerous, short, subsequent valleys by stream flow forced to the southward by the ice-damming. Such flow was effective during the advance of the ice sheet, but stronger during the waning of the ice; and probably more than one ice invasion has been concerned.

On the Ontario lowland the forced drainage was west or east, alongside the ice margin. In the Erie basin the later flow was all westward past the ice front. In the Mohawk Valley the drainage between Little Falls and Rome was turned from west to east.

The water-parting which in pre-Glacial time lay in Pennsylvania has been so changed by glacial flow that it now lies close to the Finger Lakes.

These papers were discussed together by Professors A. W. Grabau, J. W. Spencer, F. Carney, A. P. Brigham, G. F. Wright, F. B. Taylor, A. P. Coleman and H. L. Fairchild.

At 12:40 o'clock the society adjourned for luncheon, meeting again at 2:05 o'clock to continue the reading of papers. President Calvin occupied the chair. The first two papers were read by title. They were:

Some Physiographic Features of the Shawangunk Mountains: GEORGE BURBANK SHATTUCK, Poughkeepsie, N. Y.

Nantucket Shorelines, III.: F. P. GULLIVER, Norwich, Conn.

Then was presented:

Nantucket Shorelines, IV.: F. P. GULLIVER, Norwich, Conn.

The writer has not been able to continue as fully as would have been desirable the detailed study of the island of Nantucket and its changing shoreline, on account of the cost of oft-repeated observation and survey. Some results of further study since the last report made to the society were given.

The strong north and northeast storms of the past fall have closed the Haulover, and the tombolo from Wauwinet to Coskata was completed on November 12, 1908. Some old maps have been studied with reference to the former eastward extension of the oldland at Wauwinet, Coskata and Folger islands. The changes on Great Point since 1896 were compared with previous conditions and with what may be expected in future. The shoals between Nantucket and Cape Cod, and between Nantucket and Martha's Vineyard and the Hyannis shore are considered as attempts of the sea to build tombolos.

After this was presented:

Note on Striations, U-shaped Valleys and Hanging Valleys produced by other than Glacial Action: EDMUND ORIS HOVER, New York City.

The volcanic sand-blasts due to the eruption of Mt. Pelé produced striations and grooves in the material over which they passed that strongly resemble the striations and grooves produced by ice action. The heavily burdened streams of the Soufrière of St. Vincent have carved out rock channels of typical U-shape in the old lava flows of the volcano. Hanging valleys have been produced by the sea eroding more rapidly than the streams.

The paper was discussed by Professor A. Penck.

Then was read by title:

Historical Notes on Early State Surveys: GEORGE P. MERRILL, Washington, D. C.

The next paper was:

The Iron Ores of Maryland: JOSEPH T. SINGEWALD, JR., Baltimore, Md. (Introduced by W. B. Clark.)

This paper presented a brief summary of the results of an investigation carried on during the past season on the iron ores of Maryland under the auspices of the Maryland Geological Survey. Four classes of ore were recognized—limonite, hematite, magnetite and siderite. The paper presented embraced a discussion of the character and

chemical composition of each of these ores, the localities in which the deposits occur, and also their geologic and stratigraphic relations.

After this was presented:

The Shortage of Coal in the Northern Appalachian Field: I. C. WHITE, Morgantown, W. Va.

The next paper was read by title:

Glacial Character of the Yosemite Valley: FRANÇOIS MATTHES, Baltimore, Md. (Introduced by Wm. Bullock Clark.)

Then was presented:

The Mills Moraine with some discussion of the Glacial Drainage of the Longs Peak (Colorado) District: EDWARD ORTON, JR., Columbus, Ohio. (Introduced by F. P. Gulliver.)

This paper was discussed by Mr. W. T. Lee.

The next paper read was:

Quartz as a Geologic Thermometer: FRED E. WRIGHT and E. S. LARSEN, Washington, D. C.

Observations by Le Chatelier and Mallard in 1889-1890 proved that at about 570° quartz crystals undergo a reversible change, the expansion-coefficient, birefringence and circular polarization all changing abruptly. O. Mügge (*Neues Jahrbuch, Festband*, 1907, 181-196) has recently considered the problem again in detail and by means of etch figures combined with crystallographic behavior on heating found that below the inversion point quartz crystallizes in the trapezohedral-tetartohedral division of the hexagonal system, while above 570° it is trapezohedral-hemihedral. The high form is very similar to the low form and differs chiefly in the fact of its common planes of symmetry. A plate formed above 570° is trapezohedral-hemihedral, but on cooling it changes to the trapezohedral tetartohedral division, thereby losing its common planes of symmetry, which may then become twinning planes. It is to be expected, therefore, that quartz crystals thus cooled will be irregularly and intricately twinned after (1010.), while low temperature quartzes are simple or regularly twinned. It is furthermore evident, on considering the genesis of quartz at different temperatures, that intergrowths of right- and left-handed quartz are limited chiefly to quartz crystals formed below 570°. These two criteria can be used to distinguish quartz which has been formed or heated above 570° from quartz which has never reached that temperature. The object of the present investigation has been to test the general validity of the theoretical conclusions on a number of quartzes from different kinds of rocks and veins, as well as to determine more accurately the inversion temperature.

SECTIONAL MEETING FOR PAPERS ON STRATIGRAPHIC, AREAL AND PALEONTOLOGIC GEOLOGY

The section was called to order at 10 o'clock Thursday morning by Professor W. B. Clark, who was then elected presiding officer. Professor E. R. Cumings acted as secretary throughout, by request of the secretary of the society.

The first paper read was:

Occurrence of the Magothy Formation on the Atlantic Islands: ARTHUR BARNEVELD BIBBINS, Baltimore, Md.

The Magothy formation (of mid-Cretaceous age), as originally defined by Darton, was supposed by that author to be limited to the state of Maryland, although its partial equivalent, the "alternate clay-sands," was earlier mentioned by Uhler as occurring much farther northward. Recent investigations, paleobotanical and stratigraphic, by Hollick, Berry and the writer have extended the lines of the formation far southward, and northward across New Jersey and along the Atlantic Islands as far as Marthas Vineyard. The occurrence upon these islands was shown by local sections and photographs. The deposits are richly plant bearing, with grains of amber associated, as on the Magothy River. The formation suffered considerable corrugation by the great ice sheet.

The paper was discussed by Dr. David White and Professor A. B. Bibbins.

The next paper presented was:

Erosion Intervals in the Tertiary of North Carolina and Virginia and their bearing upon the Distribution of the Formations: BENJAMIN L. MILLER, South Bethlehem.

Recent investigations have furnished evidence of several uplifts and subsidences during Tertiary time in North Carolina and Virginia that have determined the present distribution of the formations. These have affected large areas at certain periods but at other times have been localized.

Then followed:

The Character and Structural Relations of the Limestones of the Piedmont in Maryland and Virginia: EDWARD B. MATTHEWS and J. S. GRANTY, Baltimore, Md., and Charlottesville, Va.

A study of the small bodies of crystalline limestones and marbles found along the western edge of the Piedmont from Pennsylvania to North Carolina shows that their occurrences mark the tops of tightly compressed anticlines. The deposits on either side are usually metamorphosed volcanics—flows and tuffs—which in the normal

section lie far beneath the limestones. The areal distribution, contacts and structural lines point to a strong overthrust fault of wide extent.

This paper was discussed by Professor J. Barrell.

After this was read:

Recurrence of the Tropidoleptus Fauna and the Geographic Range of Certain Species in the Chemung of Maryland: CHARLES K. SWARTZ, Baltimore, Md.

The recurrence of *Tropidoleptus* and associated species of Hamilton type above the base of the Chemung of Maryland was noted. Certain diagnostic species of the Chemung, particularly those of the genera *Douvillina* and *Dalmanella*, appear to be of rare occurrence east of the Allegheny Front. The significance of this fact was discussed.

Discussion of the foregoing paper was participated in by Professors H. S. Williams, H. F. Cleland, Charles Schuchert, C. K. Swartz, J. M. Clarke, Stuart Weller, E. R. Cumings and C. S. Prosser.

Then was read:

The Geological Distribution of the Mesozoic and Cenozoic Echinodermata of the United States: WM. BULLOCK CLARK and M. W. TWITCHELL, Baltimore, Md., and Columbia, S. C.

The authors presented the results of an investigation of the Mesozoic and Cenozoic echinodermata of the United States, particularly in reference to the geological distribution of the forms studied. Representatives of the echinodermata are found at most horizons, but are numerous and significant in the Cenozoic and Tertiary rocks, where they at times become important forms for the determination of geologic horizons. The Upper Cretaceous formations both of the Atlantic and Gulf states have afforded a large number of important species.

The paper was discussed by Dr. J. M. Clarke and Professor W. B. Clark.

The next paper read was:

On the Age of the Gaspé Sandstone: HENRY S. WILLIAMS, Ithaca, N. Y.

A review of the evidences upon which has been based the opinion that the marine fauna at the base of the Gaspé sandstone is of the Hamiltonian epoch, and a presentation of the evidence for the view that these marine beds, as well as those of Pictou iron ore beds of Nova Scotia, Moose River sandstone of Maine and the upper beds of the St. Helen's Island conglomerate and of Côte St. Paul, are not of later age than the Oriskany beds immediately underlying the Onondaga limestone

of North Cayuga, Ontario or Schoharie grit of eastern New York, at which epoch it is inferred marine connection with the Atlantic basin was cut off.

The Owl's Head and Chaudière River beds were explained by supposing the opening of a channel westward, connecting with Indiana basin and southwest at beginning of the succeeding Onondaga epoch.

The paper was discussed by Professors J. M. Clarke, Charles Schuchert, H. S. Williams and A. W. Grabau.

The section adjourned at 12:30 p.m. and met again at 2:15 p.m. with Professor W. B. Clark in the chair.

The following two papers were read by title:

The Aftonian Sands and Gravels in Western Iowa: BOHUMIL SHIMEK, Iowa City, Iowa.

An Aftonian Mammalian Fauna: SAMUEL CALVIN, Iowa City, Iowa.

Then was presented:

The Brachiopoda of the Richmond Group: AUGUST F. FOERSTE, Dayton, Ohio.

In the area dominated by the Cincinnati geantiline there have been several invasions of the brachiopoda considered most typical of the Richmond group. The first of these occurred near the middle of the deposition of the Arnheim bed. The Richmond group of the Mississippi Valley, as far as may be determined from a study of the brachiopoda, finds nearer representatives in the upper or Blanchester division of the Waynesville bed and in the Liberty bed, than in the Arnheim, lower Waynesville or Whitewater beds. A study of the distribution of the brachiopoda in Ohio, Indiana and Kentucky suggests that the centers of distribution lay more frequently toward the northeast than toward the northwest or west of the present areas of exposure. To account for this it is imagined that the Richmond group of the Ohio Valley was connected with that of the Mississippi Valley by way of northern Indiana and Illinois. Possibly, if the areas now covered by overlying formations could be exposed, the Richmond brachiopoda would be found to be absent in southern Indiana and Illinois and in western Kentucky, west of the present areas of exposure of these fossils in the region of the Cincinnati geantiline. Lithological conditions within the areas dominated by this geantiline favor this view.

Professor E. R. Cumings discussed this paper.

After this, the following paper was read:

The Trap Sheets of the Lake Nipigon Basin: ALFRED W. G. WILSON, Montreal, Canada.

The well-known trap sheets which form one of the most salient geologic features of the north shore of Lake Superior, are usually regarded as intrusive in origin and of the nature of laccolithic sills. In the basin of Lake Nipigon, lying north of Lake Superior, on the Laurentian peneplain, the trap sheets are found to rest either directly upon the Archean rocks or upon small outliers of the sediments, often many miles distant from the main areas of similar age. The traps are known to rest unconformably upon at least five different earlier formations. This unconformity can be explained by attributing to the fluid traps the ability to insinuate themselves, in an extremely intricate manner and over a very large area, between overlying sediments and underlying crystallines, here and there masses of the sediments remaining so firmly attached to the bed on which they rested that the traps flowed over and around them, cutting across the beds.

While many of the trap sheets along the north shore of Lake Superior are undoubtedly laccolithic sills, still the writer is inclined to believe that the balance of evidence shows that these sills are confined largely to the areas underlain by sediments of later date than the Archean. A simpler explanation, and one that appeals to the writer as more reasonable, of the relations known to exist between these trap sheets and the underlying rocks in the Nipigon basin, is that, at least along the line of the escarpments which mark the boundary between the sediments and the Archean areas to the north and out upon the old land itself, the same traps flowed over an eroded surface of subaerial origin.

Incidentally there is strong, though not conclusive, evidence for considering that these flows might be even of post-Cretaceous age.

This paper was discussed by Professors A. W. Grabau, A. W. G. Wilson, A. C. Lane and A. F. Foerste.

Then was read:

Reconnaissance in Arizona and Western New Mexico along the Santa Fé Railroad: N. H. DARTON, Washington, D. C.

The reconnaissance was made for the purpose of ascertaining the prospects for deep wells to supply water to the railroad and settlements along its line. The region examined was from ten to forty miles wide and in this area the principal structural and stratigraphic features of formations from Cambrian to Cretaceous were determined.

This was followed by the reading of:

Geologic Studies in the Alaska Peninsula: WALLACE W. ATWOOD. (Introduced by A. H. Brooks.)

Detailed work was done in the vicinity of Chignik, Balboa and Herendeen bays and on the Island of Unga. The Balboa-Herendeen Bay district was selected as a type area in the peninsula, and detailed studies were pursued in the hope of working out a key to the general geologic conditions of this portion of Alaska.

The formations exposed include the Upper Jurassic, Lower and Upper Cretaceous, marine and freshwater Eocene, Miocene, possibly some Pliocene, Pleistocene and recent Kenai plants were found associated with marine invertebrate shells of Upper Eocene age.

Vast quantities of igneous rocks have been intruded into the sedimentary series, and overlying a portion of the area there are volcanic tuffs and basic flows of post-Miocene age.

Coal occurs in the Upper Cretaceous and Eocene. Gold and copper prospects were examined at several localities.

Then was presented:

Present Knowledge of the Oklahoma Red Beds: CHARLES N. GOULD, Norman, Okla.

After this was read:

The Fauna of the Fern Glen Formation: STUART WELLER, Chicago, Ill.

The Fern Glen formation is typically developed in St. Louis and Jefferson counties, Missouri, and Monroe County, Illinois. It lies at the summit of the Kinderhook group and consists of beds of red calcareous shales and red limestones, with a maximum thickness of about forty feet. The upper beds are more greenish in color and merge gradually into the superjacent Burlington limestone. The fauna is distinctly a member of the southern group of Kinderhook faunas and consists for the most part of corals, crinoids and brachiopods, with a few blastoids, molluscs and trilobites. Many of the species are undescribed, although more or less closely related to known forms in other Kinderhook faunas or in the Burlington limestone. The correlation of the fauna is with those of the basal Knobstone shales of Kentucky, the St. Joe marble of Arkansas and the Lake Valley beds of New Mexico.

The paper was discussed by Professors Charles Schuchert, Stuart Weller and E. O. Ulrich.

The next two papers were read by title:

Age and Geologic Relations of the Sankaty Beds, Nantucket: W. O. CHAMBERLAIN, Boston, Mass.

Age and Relations of the Sankaty Beds: H. W. SHIMER, Boston, Mass. (Introduced by W. O. Crosby.)

Then the following paper was read:

Some Features of the Wisconsin Middle Devonian:

H. F. CLELAND, Williamstown, Mass.

This paper gave the results of a study of all the outcrops, as far as known, of the Wisconsin Devonian and their contained faunas. In it were discussed: (1) the relation of the strata to those above and below, (2) the unconformities, (3) the lithological characters and (4) the character, relationships and geographical distribution of the faunas.

Professors Charles Schuchert, A. W. Grabau and H. M. Ami participated in the discussion of this paper.

The next paper read was:

Ice-borne Boulder Deposits in mid-Carboniferous Marine Shales: JOSEPH A. TAFF, Washington, D. C.

Great numbers of boulders and other erratic fragmental rock debris occur in the Caney formation of the Ouachita Mountain region in southeastern Oklahoma. The erratic material consists of boulders, cobbles and small rock fragments of three general classes, namely: (1) limestones, siliceous, argillaceous and magnesian; (2) flints, cherts and (3) quartzites.

The limestones are of various textures and colors, some of which partake of the nature of the quartzites, while others are argillaceous; others yet appear to be dolomitic or perhaps dolomites. Many of the limestone boulders are massive and homogeneous, while others are distinctly stratified and contain two or more classes of limestone, or strata of limestone and flint.

Flint and chert boulders are also of common occurrence, and in places are even more abundant than the limestone boulders. Certain of these flints are stratified or bedded and are black or bluish in color, while others are massive, chalcidonic in character and contain inclusions of drusy quartz. Among these are many of conglomerate and brecciated nature.

The third group in the general classification of these erratics includes quartzites of dark and reddish hues.

These erratic boulders vary in size from small pebbles to boulders of enormous size, a few of which attain lengths of more than fifty feet. Many of the smaller boulders are more or less rounded, while a few are quite perfectly so. The larger ones are, as a rule, angular.

At three separate localities in the Ouachita Mountain region certain of the limestone and flint boulders contain grooves and striæ as if produced by the action of shore ice. Certain of these striæ also resemble the markings of slickensided surfaces. The evidence as to the origin of these gouged surfaces is not conclusive.

The erratic boulders contain a comparatively abundant Ordovician and Silurian fauna. The boulders are promiscuously scattered in the Caney formation of black and blue shale with local beds of sandstone in the upper part.

The Caney formation is several hundred feet thick and contains limy concretions or segregations, associated with the erratic boulders and elsewhere, that contain an abundant fauna of late Mississippian or early Pennsylvanian age.

The area of boulder-bearing beds of the Caney formation, as now known, is within the Ouachita Mountain uplift in Oklahoma that extends within a few miles of the Arkansas line to the west end near Atoka.

The structure of the region is typically Appalachian, the rocks being closely folded and thrust northward.

Upon comparison, both lithologically and faunally, the erratic boulders are found to contain identical characteristics in the Cambro-Ordovician and Silurian rocks in the Ouachita Mountain region of Oklahoma and in the Cambro-Ordovician section in north-central Texas. There are evidences of emergence of the rocks of mid-Carboniferous time in the western part of the Arbuckle uplift and in the Texas region to the southwest that affect the Cambro-Ordovician and Silurian rocks. The tentative conclusion is that the boulders were transported from a land to the south by the agencies of ice.

This paper was discussed by Messrs. David White, W. C. Alden and J. A. Taff.

The last paper on the sectional program was:

Relationships of the Pennsylvanian and Permian Faunas of Kansas and their Correlation with Similar Faunas of the Urals: J. W. BEEDE, Bloomington, Ind.

Owing to physical changes which occurred during the close of Pennsylvanian time, there occurred a great reduction of Pennsylvanian species, followed by the introduction of Permian species. This introduction of new species becomes very noticeable in the Elmdale formation and its base is considered the base of the Kansas Permian. The Permian, as here understood, includes the

Artinskian and "Permo-Carboniferous" of Eurasia.

REPORTS OF COMMITTEES

Through Mr. Arthur Keith the Committee on Geologic Nomenclature reported that it had organized by the election of Professor T. C. Chamberlin as chairman and Mr. A. Keith as secretary. The committee is constituted as follows:

For the Geological Society of America: Professors T. C. Chamberlin and W. B. Scott.

For the U. S. Geological Survey. Mr. Arthur Keith and Dr. David White.

For the Association of State Geologists: Dr. J. M. Clarke and Professor E. A. Smith.

For Canada—Geological Survey: Professor F. D. Adams. Other official surveys: Dr. W. G. Miller.

For Mexico: Dr. J. G. Aguilera and Dr. C. Burckhardt.

The Photograph Committee, Mr. N. H. Darton, reported that there had been few accessions during the year and practically no use of the collection.

On account of the length of the program the council formed a special section for the consideration of certain papers forming part of a symposium on correlation which had been arranged for by Mr. Bailey Willis, chairman, and Dr. F. P. Gulliver, secretary, of Section E (Geology and Geography) of the American Association for the Advancement of Science. For the sake of record the whole list of these papers, with the times when they were read, follows.

MONDAY, DECEMBER 28

Before Section E. (By title in G. S. A. program.)

Pre-Cambrian

11:00 A.M. to 12:10 P.M.

C. R. Van Hise: "Principles of Pre-Cambrian Correlation."

F. D. Adams: "The Basis of Pre-Cambrian Correlation."

Early and Middle Paleozoic

3:30 to 4:00 P.M.

C. D. Walcott: "Evolution of Early Paleozoic Faunas in Relation to their Environment."

4:00 to 5:50 P.M.

A. W. Grabau: "Physical and Faunal Evolution of North America in the Late Ordovician, Silurian and Devonian Time."

4:50 to 5:30 P.M.

Stuart Weller: "Correlation of Middle and Upper Devonian and Mississippian Faunas of North America."

TUESDAY, DECEMBER 29

Before a temporary section of the G. S. A.

Late Paleozoic

11:00 A.M. to 12:05 P.M.

G. H. Girty: "Physical and Faunal Changes of Pennsylvanian and Permian in North America."

David White: "The Upper Paleozoic Floras, their Succession and Range."

Vertebrates

2:00 to 3:15 P.M.

S. W. Williston: "Environmental Relations of the Early Vertebrates."

H. F. Osborn: "Environment and Relations of the Cenozoic Mammalia."

Mesozoic and Tertiary

3:15 to 4:00 P.M.

T. W. Stanton: "Succession and Distribution of Later Mesozoic Invertebrate Faunas."

4:00 to 5:15 P.M.

W. H. Dall: "Conditions Governing the Evolution and Distribution of Tertiary Faunas."

Ralph Arnold: "Environment of the Tertiary Faunas of the Pacific Coast."

WEDNESDAY, DECEMBER 30

Before a temporary section of the G. S. A.

Tertiary and Quaternary

10:50 to 11:25 A.M.

F. H. Knowlton: "Succession and Range of Mesozoic and Tertiary Floras."

11:25 A.M. to 12:25 P.M.

R. D. Salisbury: "Physical Geography of the Pleistocene with Special Reference to Conditions Bearing on Correlation."

D. T. MacDougal: "Origination of Self-generating Matter and the Influence of Aridity upon its Evolutionary Development."

2:30 to 3:45 P.M.

T. C. Chamberlin: "Diastrophism as the Ultimate Basis of Correlation."

After the reading of scientific papers had been finished, the society met again in general session and Professor J. M. Clarke proposed a vote of thanks to the citizens of Baltimore, the authorities of the Johns Hopkins University and in particular to the members of the department of geology for the welcome accorded to the society and the particularly complete arrangements made for the work of the meeting and the comfort and enjoyment of those in attendance. The vote was

most heartily passed and was responded to by Professor W. B. Clark in behalf of the Baltimoreans concerned.

The society adjourned shortly before 5:00 P.M., on Thursday, December 31.

The following officers were elected by the society for the year 1909:

President—Grove K. Gilbert, Washington, D. C.

First Vice-President—Frank D. Adams, Montreal, Canada.

Second Vice-President—John M. Clarke, Albany, N. Y.

Secretary—Edmund Otis Hovey, New York City.

Treasurer—William Bullock Clark, Baltimore, Md.

Editor—Joseph Stanley-Brown, Cold Spring Harbor, N. Y.

Librarian—H. P. Cushing, Cleveland, Ohio.

Councilors (1908-1911)—George Otis Smith, Washington, D. C., and Henry S. Washington, Locust, N. J.

The following were elected as fellows of the society: Elliot Blackwelder, Madison, Wis.; William Phipps Blake, Tucson, Ariz.; Charles Wilson Brown, Providence, R. I.; Frank Carney, Granville, Ohio; Edward Salisbury Dana, New Haven, Conn.; Cassius Asa Fisher, Washington, D. C.; Albert Johannsen, Washington, D. C.; Geo. Frederick Kay, Iowa City, Iowa; Henry Landes, Seattle, Wash.; George Burr Richardson, Washington, D. C.; Joaquim Candido da Costa Sena, Ouro Preto, Minas, Brazil; Earle Sloan, Charleston, S. C.; George Willis Stose, Washington, D. C.; Charles Kephart Swartz, Baltimore, Md.

One hundred thirty-five fellows were in attendance, making this second Baltimore meeting the largest in the history of the society. The council voted to hold the next winter meeting in Boston and Cambridge.

EDMUND OTIS HOVEY,
Secretary

SOCIETIES AND ACADEMIES

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 455th meeting was held February 20, 1909, with President Palmer in the chair. Dr. M. W. Lyon, Jr., exhibited the skins of two weasels from the vicinity of Washington, D. C. One was taken in the middle of the relatively mild winter of 1906-7 and showed the light brown pelage of long fur, characteristic of the winter pelage of weasels in this latitude. The other was taken in the latter part of March, 1904, and was mainly in the white winter pelage characteristic of weasels in higher latitudes. The middle line of the back

showed the dark brown shorter summer pelage coming in. The winter of 1903-4 was colder than that of 1906-7. Whether that had anything to do with causing a white pelage instead of a light brown one could not be said.

The following communications were presented:

Some Japanese Entomologists and their Laboratories, with Notes on the Introduction of Parasites of the Gypsy Moth: L. O. HOWARD.

Dr. Howard spoke of some Japanese entomologists and their laboratories, and of the recent work in importing parasites of the gypsy moth and the brown-tail moth. He described some of the recent innovations in the large-scale experiment which has been carried on for three years by the Bureau of Entomology of the U. S. Department of Agriculture in the importation of parasites from Europe and from Japan, most of which have been mentioned in the annual report of the Chief of the Bureau of Entomology for 1908. He spoke especially of a trip to Japan taken during the summer of 1908 by Professor Trevor Kincaid, of the University of Washington (Seattle), as an agent of the bureau, to collect and send to the United States the Japanese parasites of the gypsy moth. This expedition was highly successful, and Mr. Kincaid met with the most gracious courtesy and the most hearty cooperation on the part of the Japanese entomologists. The talk was illustrated by lantern slides showing groups of Japanese entomologists at different agricultural colleges and experiment stations, as well as at private stations, and also of the experiment station buildings and laboratories.

Some Remarkable Phenomena Occurring in the Breeding of Varieties of Dianthus: J. B. NORTON.

Since 1904 several hundred seedling carnations have been grown each year by Mr. E. M. Byrnes, of the Bureau of Plant Industry, in the greenhouses of the Department of Agriculture. From the notes and records kept of these seedlings by the speaker, it was found that about 23 per cent. of the seedlings were typical single flowered, the remainder being double. The double flowers could be divided into two groups—standard doubles, i. e., like the parent varieties, and full doubles, or "bull-heads"; the latter class averaging about 25 per cent. of the total number of seedlings. The close agreement of these percentages was that of a second generation of a Mendelian hybrid, which led to the prediction that the commercial carnation was a hybrid type and that the single and bull-head types were the extracted pure parent

forms. Experiments were carried on to determine this point by crossing single-flowered plants with the pollen of the full doubles. Out of three hundred seedlings in 1906 from crosses of this kind only two singles were found, the remainder being standard, or hybrid doubles. These two singles could have been from accidental pollination with pollen from other singles, since the flowers were not covered. Singles crossed with singles gave nothing but single-flowered seedlings. The full doubles failed to set seed on account of their defective ovaries, which were often changed into collections of petal-like organs. This work has since been repeated by other breeders with perfect results under control conditions. The double flowers are interesting in that doubling is accomplished in the same flower by increase in the number of whorls of petals, by change of stamens into petals, and by basal branching of large petals into a number of smaller ones. These three methods seem to be associated as one character. In the intermediate hybrid the three methods of doubling all appear, but in reduced form.

For many generations the parents of the American carnation varieties have been uniformly of the hybrid type, but as yet we have no instance of it reproducing true to type by seed, the two parent types constantly reappearing in about their normal proportions. Other characters, such as dwarf habit, short calyx, clove scent, color, variegated petals, etc., seem to follow the same law of heredity. Since *Dianthus caryophyllus* is normally strongly proterandrous and carnation breeders in the past have uniformly practised wide cross breeding, so that, if anything, the vigor of the type is constantly increasing, it is interesting to note the occurrence of Mendelism in this group, as recent unsupported theories have claimed that such should not be the case.

M. C. MARSH,
Recording Secretary

THE TORREY BOTANICAL CLUB

The meeting of February 24 was held at the Museum of the New York Botanical Garden at 3:30 P.M. In the absence of the president and both vice-presidents, Mr. Fred J. Seaver was called to the chair.

The following scientific program was presented:
Collecting Fungi in Jamaica: Dr. W. A. MUESEBELL.

This paper has been published in the February *Journal of the New York Botanical Garden*.

Cypripedium in the Light of its Segregates: Mr. G. V. NASH.

Mr. Nash exhibited living plants and herbarium specimens illustrating the four segregates now recognized by orchidologists, and formally considered as parts of the genus *Cypripedium*. These segregates are *Cypripedium*, *Selenipedium*, *Paphiopedilum* and *Phragmipedium*. These divide themselves into two groups. In the first group are *Cypripedium* and *Selenipedium*, characterized by the usually long, leafy stem and broad, flat, thin, many-nerved leaves which are convolute in venation, and the withering perianth persistent on the ovary. In *Cypripedium* the ovary is one-celled, and the seeds elongate with a thin testa. This genus is of north temperate distribution, its representatives, about thirty in number, being found in North America, Europe and Asia.

The other genus of this group, *Selenipedium*, has a three-celled ovary, and the seeds nearly globose with a crustaceous testa. This is found from Panama to northern South America and is rare. It contains only three species, which are seldom seen in cultivation.

The second group is at once recognized by the conduplicate venation of its long, narrow, fleshy, strap-shaped leaves and the deciduous perianth. The flowers are borne on scapes, which are rarely somewhat leafy below. To this group belong the remaining two genera, *Paphiopedilum* and *Phragmipedium*. In the former the ovary is one-celled and the sepals imbricate in the bud. The most evident character, however, differentiating this at once from *Phragmipedium*, is in the lip which has the margin of the opening straight, not infolded. The scape is also commonly one-flowered, the exception being with more than one. There are some fifty species known in this genus, which is entirely old world, being generally distributed in tropical Asia and the Malay region.

The genus *Phragmipedium* is entirely new world, occurring in northern South America and Panama. It contains in the neighborhood of a dozen species, and is at once separated from *Paphiopedilum* by the character of the lip in which the margin of the opening is marked by a broad infolded portion. In addition to this the ovary is three-celled and the sepals valvate in the bud; the scape, moreover, bears several, sometimes many, flowers.

We have then in the new world three of the genera, two—*Phragmipedium* and *Selenipedium*—not known elsewhere, and *Cypripedium*, which it shares in distribution with the old world. The only strictly old world genus is *Paphiopedilum*.

A PLEA FOR A WIDER AND BETTER EXTENSION OF THE KNOWLEDGE OF SANITARY SCIENCE¹

SANITARY science is young, or, at least, that much may be said of the science as we know it to-day, and consequently I presume it is scarcely reasonable to expect the public at large to be very well posted as to its latest discoveries and improvements. But so much depends upon an intelligent cooperation on the part of the masses of the people in the matter of the proper application of sanitary principles that every effort should be made to hasten the day when sound doctrine shall underlie each act of the community that is made in the interest of public health.

In view of the great width of the field which suggests itself, some kind of reduction will be necessary for our present purpose. Therefore, may I ask your attention to two items with which I have had more or less to do, viz., "water" and "air"?

A great deal has been accomplished in recent years in the matter of educating the public in the proper care of domestic water supplies; but much misunderstanding yet remains for removal, and old-time traditions are with us still.

Did you ever hear that a horse will drink no water that is of inferior quality? Such a statement has been made to me many a time and has been insisted upon as a fact. The fairy tale is pretty widely distributed, especially in country districts, and it is received as true, although it needs but a

¹ Founder's Day address, given at Lafayette College October 21, 1908.

little observation of the habits of horses to establish its fallacy. Would you, as intelligent people, who have watched horses upon occasion, care to pin your faith upon the "horse-test" as indicating the purity of your household drinking water?

When I was a boy the belief existed that the presence of many flies tended towards a healthful summer, because they were held to be the means of removal of much waste material which would otherwise decay and taint the atmosphere. We now know that flies are a source of danger in that they do not wipe their feet before crawling over our food. In this connection note the disastrous typhoid fever outbreaks in our military camps during the Spanish war. Those epidemics were occasioned by the inoculation of food by flies; flies that visited the latrines first and the kitchens afterwards.

Returning now to the water question, the time-honored dictum that a clear, bright water is of necessity a wholesome one is also still widely trusted; but it reminds me of the ruling of a Mississippi chancellor in a case with which I was once connected. His honor threw all the expert testimony out of court with the remark that the ordinary citizen is able well enough to tell whether or not a given water is fit to drink. To illustrate how far the court fell short of the truth in this instance, let me say that not long ago the clear and bright effluent from the Saratoga sewage septic tank was placed in a show window in western New York alongside of an exhibit of the local water supply, to the apparent disadvantage of the latter. Poor as the town water was, it could scarcely have been fair to compare it with filtered sewage and yet his honor from Mississippi would have judged otherwise.

The "test of experience" is constantly appealed to in support of the alleged purity of some favorite water, and the plea

that "my family has used the supply for half a century" is considered an argument beyond danger of refutation, it being overlooked that a family, or even several families, can not furnish a sufficient number of persons to make the "experience test" valuable; for, be it remembered, a water known to be dangerously polluted will not transmit disease to all, nor nearly all, of those who drink it. As a matter of fact, when one considers the question from a numerical standpoint, basing his investigation upon the population of a large community, the conclusion is forced upon him that the per capita danger from polluted water is really small. Thus, in a city of 100,000 inhabitants, which I have in mind, the high typhoid death rate, manifestly caused by bad water, was about 90 per year; which means that over 99,000 of the people did not have the disease at all.

Now how about this great majority of the citizens that escaped. They would not be likely to testify as to the dangers of the water supply. As you see, the risk is small and it takes a large community to make data about it valuable, but relatively small though it be, it nevertheless is a good investment for a city to avoid it, because human life has a money value and the town which cuts its typhoid rate in half by the erection of a filter plant receives very quick return for the funds expended.

Doubtless one reason why so many people deny the existence of danger lurking in some specific drinking water is because of the non-dramatic character of the attack.

Let us suppose that a city has a yearly typhoid death rate of 75, which means that 750 people per 100,000 inhabitants have the disease each year and that 75 of them die. The impression upon the community is not really felt except by those whose homes are invaded and the remainder of the population would be likely to resort to

the old story "we have used the water for years without harm, etc." What do you think would happen in such a city if some trolley road were so badly managed as to kill 75 people every year and injure 675 others? Do you fancy it would be long before there would be mob demonstration against such a road? Or again, suppose a foreign warship should drop shells into the streets of such a town, killing from one to two people weekly and wounding nine times as many; would the people who had been hit be likely to listen with patience to such of their neighbors as claimed that because they had not been struck they doubted if there were any war vessel in the river after all?

Let us glance for a moment at the question of atmospheric air.

We all breathe, but we have been doing it so long and for the most part so easily, that a great many of us forget that we do it at all. We also eat, but the occasions for eating produce an impression upon us. Moreover, we are to a large degree particular as to the quality of the things we eat. Fancy trying to induce your employees to accept improper and tainted food. Such an effort would very probably and properly breed a riot, and yet those same people will sleep in badly overcrowded rooms and will likely complain of drafts if the windows be open. Without food they could live a week and more, while with no air they could not survive five minutes, yet one hears but rarely any comment upon the quality of that necessity of life which is so vastly more important than food.

It doubtless would be a surprising statement to preach very widely, but the cold fact remains that bad air is responsible for more deaths than alcohol. Much as we deplore the evil effects of strong drink, its victims, both innocent and guilty, are few compared with those of the "great white

plague." Are you aware that practically ten per cent. of all those who died in the state of New York during the past year died of consumption, a disease which is closely connected with polluted air? Please remember those figures, one in every ten.

This has been termed "the age of hygiene" and I think the expression a good one. Much hygienic advancement has been accomplished, but a great deal more remains to be secured. Perhaps as noteworthy an instance of improvement as can be quoted is the smaller amount of spitting one sees in the street cars. That is a most encouraging fact, but why should not ventilation of the cars be insisted upon also. Given a crowded car upon a misty evening in January when the workers are returning home with garments soiled and wet, if the ventilators be closed, as they commonly are, the air within is utterly unfit for breathing. If the two halves of the car roof were hinged upon a sort of ridge pole and occasionally thrown open for a short time, much improvement in the air would result and that too without complaint, because the public will accept a great inrush of cold air for a moment when they would object to a small stream of continuous flow.

As already said, much has been done, but the question is often asked, is there any substantial benefit to show for it? Are we really better off than our forefathers because we possess these so-called improvements?

There is but one answer to such a question and that is to ask the inquirer to consult the recorded death rates and to note that the total rate for London has fallen 75 per cent. in less than 300 years; that consumption in the English army has lessened since an increased air space has been provided in barracks; that small-pox is now practically unknown in the German army, because of compulsory vaccination; and that typhoid fever has been reduced in

some municipalities as much as 70 per cent. by the introduction of filtered water.

It being a fact beyond doubt that good sanitary knowledge is a real asset of a community, the question is in order, how are we to secure a better general understanding of sanitary principles? How are the people, particularly the poorer people, to be educated along such lines?

Of all members of a community, the physicians are the ones towards whom we most quickly look for instruction in matters sanitary. Their profession primarily, of course, deals with the combating of maladies already in evidence, but they have also an undoubted duty to perform in protecting men from disease as well as in curing them of it. That being granted, it is pertinent to inquire if the medical schools provide such instruction as will place their graduates in a position to properly meet their double responsibility. So far as I can discover, such a question must too often be answered in the negative. It is expected of a physician that he should speak *ex-cathedra* upon topics dealing with the protection of health, but, aside from some noteworthy exceptions, the average doctor has, through no fault of his own, been unprovided with very strong foundations in sanitary science.

Let us now look at another group of men with responsibilities.

Whenever human beings are gathered together in organized bodies, as during military service, those in control of them have the serious task of safeguarding their health and it goes without saying that such persons should be equal to performing the duties of their office. Of the amount of knowledge of a sanitary kind possessed by officers of the regular army I can not speak, although my belief is that those of the medical staff, at any rate, are well-posted men. All of us must surely allow no small measure of praise to the officers of the

Japanese army in view of the excellent results secured by them during the Russian war.

What can be said, however, of the expert knowledge of our officers of militia? Simply nothing. As a class, they have no proper understanding of the sanitary needs of large groups of men and yet they have been and may be again suddenly called upon to command bodies of troops in the field. Of course the line officers have those of the medical staff to lean upon, but even so, an ignorant line commander can not be educated while on the march and he can readily place his men amid such unsanitary surroundings as will produce evils exceeding the power of his medical adviser to rectify. We all know the general method followed for the selection of militia officers and are aware that popularity, coupled with a knowledge of tactics, constitutes the total requirement for election. An examination has to be passed before a commission is secured, but in that examination the questions touching upon the sanitary care of troops are few indeed. Imagine a detachment of state soldiers suddenly deprived of meat food. Is it likely that many of their line officers would be capable of suggesting a vegetable high in nitrogen to replace it?

I contend that those who are responsible for the safety of enlisted men should be as well qualified to protect them from an invasion of disease as from the bullets of the enemy. For it has been well said that if we could eliminate disease from army life, then war would become an international pastime somewhat less dangerous per capita per hour for those engaged than college football. And further, not only should the officers be posted in matters sanitary, but the men themselves should receive some sort of instruction calculated to increase their safety, efficiency and comfort.

As akin to what we have said, our thoughts now turn to another group of responsible leaders who are placed in control of bodies of very ignorant laborers. I refer to our civil engineers. Such men have a double responsibility, for it is their duty not only to protect the health of their employees, but they are also bound to guard against the very real danger of contamination reaching some neighboring town's water supply by reason of the laborers camping upon the watershed. Many an epidemic has been traced to that source of pollution.

The curricula of our engineering schools are not destitute of instruction in sanitary science, but the time devoted to it is distinctly small.

Let us change the point of view for a moment and ask how much of this kind of information is possessed by our graduate trained nurses. With what confidence could you depend upon their knowledge of the dangers lurking in water or milk and the best way to guard against them? Are they as posted as they should be upon the longevity of the more common disease germs and do they know why corrosive sublimate is not uniformly a good disinfectant for tuberculosis sputum? The answer is evident, but the blame is not with them. It lies with those who mapped out their line of training.

As a final group for our consideration let us turn towards the children in our schools and the students in some of our non-technical colleges. Are they receiving the amount and particularly the kind of sanitary instruction fitted to their future needs as intelligent citizens? Please note that I dwell upon the quality as well as upon the quantity of teaching they receive. If they be taught to clean the outside only of the cup and the platter; if they be so misled as to confound a deodorizer with a disinfectant; if they be induced to believe

that straining off that which is apparent to the eye will render a polluted water safely potable, then I claim that their little knowledge is a very dangerous thing and distinctly worse than none at all.

Of all the people in the nation, the ones from whom we expect the greatest returns for our efforts in sanitary instruction are those who are sufficiently young to approach the subject with no previous prejudices. One of England's greatest surgeons, now a few years dead, was a strong opponent of the germ theory of pus formation. He expressed himself as willing to dress his patients' wounds with such bacteria if he could but get enough of them for the purpose. Men so set in their ways do not easily respond to any form of conversion. It is with those who are now young that we must lodge our hope and it is among them that we should push our sanitary propaganda, but let us advance it evenly and by first-class instructors.

A word as to what I mean by such terms.

An immense amount of effort has been expended in the cause of temperance and excellent results have been secured, but let me ask, has any similar crusade been pushed with equal vigor against the spread of other forms of intoxication; that, for instance, produced by the toxin of bacillus typhosus or the still more serious bacillus of tuberculosis? Have you any idea of the relative numbers of victims claimed by alcohol, typhoid fever and consumption each year? The effects of alcoholism are more dramatic and more disgusting and therefore more quickly command our attention, but as to the question of annual fatality and suffering produced, it is the least evil of the three.

Deaths in
State of New
York, 1907

From alcoholism	1,023
From typhoid fever	1,688
From consumption	14,406

When a man drinks alcohol the object lesson for the onlooker comes speedily and it is easy for the reformer to enlist his sympathy in a temperance movement. But when one breathes in foul air loaded with the bacilli of tuberculosis no immediate results are observed and the opportunity does not present itself of closely connecting the inoculation with the subsequent development of the disease.

Please do not misunderstand me. I am very far indeed from wishing to in any way lessen the temperance movement, but I can not help feeling that the plan of campaign of that movement might very properly be studied, and possibly applied, for the arrest of the other two disorders mentioned above.¹

Education is what is needed, not only for the purpose of coping with alcoholism, but with a view of attacking the other ills as well. You are aware, doubtless, that the temperance reformers have advanced their cause until it is a strong factor in matters political, and that they have secured the passage of laws ordering that public instruction be given as to the dangers incident to the use of alcohol. Have you ever heard of so considerable a movement being inaugurated to check the ravages of consumption or typhoid fever? Earnest efforts are now afoot to do something in that line and a good deal has been really accomplished, but those engaged in the work by no means exhibit the broad front and army-like march of the temperance organization. The people as a whole

are not sufficiently educated as yet to appreciate the necessity of decided action and their sympathy with the needed reform is not awakened.

May I digress a moment and venture a word as to the wave of interest in the care and cure of consumption as we now see it in northern New York?

In the city from which I come we are plentifully supplied with committees of devoted men and women who contribute of their own means and ask pecuniary aid from others, giving meanwhile much of their time and energy for the purpose of relieving the wants and lessening the sufferings of their consumptive neighbors. The cause is such a noble one and the movement is so single-hearted that I feel badly indeed to predict its failure. Yet I believe that it must fail and for this reason. Successful handling of the consumptive poor must be the duty of public officers backed by the public purse. Funds raised by subscription and applied by voluntary workers can not grapple with the situation, because of the practically chronic character of the disease. If the community were invaded by cholera, yellow fever or the black death, and if the dead were being removed in furniture vans, as they were at Messina in 1887, then the "contribution-volunteer system" would work to perfection, because the people will always labor enthusiastically and make any amount of sacrifice to resist an attack which is quick, sharp and decisive; but if the service required be continuous, the same ten or twenty years hence as it is to-day, then the interest begins to weaken after a time, the treasury becomes empty and the movement slackens. There is just one place whence the funds for the care of the consumptive poor should come, and that is the tax budget. Is not this a plea for the education, not only of the officials who make up the budget, but also of those who vote them into office?

¹ My reason for selecting alcoholism for comparison is because of the excellent organization of those who oppose it, an organization worthy of being copied for more general use. It should be noted, moreover, that I have treated alcoholism as a disease and have touched upon its death rate only. It is scarcely necessary to add that the moral side, which is of such great importance in this affliction, does not enter the figures as given.

And finally a word as to the second point I mentioned some lines back.

Our young people should get their sanitary instruction from thoroughly competent sources, or they would do better to have none at all, because false teaching is dangerous. Books are often much out of date and it is always better to rely upon the freshly accumulated experience of those who are in touch with the active problems of the day. Even though the hours must be few during which the student is in contact with some one who is master of his specialty, yet the benefit derived greatly surpasses that obtained during a longer period of second-hand teaching.

There is no branch of instruction that lends itself more readily to what has been termed the "alumni lecture course" than does that of sanitary science.

Subsequent to the lecture a thorough quiz could be readily carried on by a person detailed for that purpose, but it should be based upon the points developed by the lecture and the latter should be given by a man who is thoroughly competent and actively engaged in his profession.

W. P. MASON

THE FUTURE OF AGRICULTURAL CHEMISTRY¹

It may seem uncalled for at a time when agricultural chemistry has been undergoing such rapid evolution and expansion in the United States, to enter upon a discussion of its future. It is, nevertheless, true that conditions are now developing in this and other countries and have reached their culmination in Germany, which make a discussion of this subject not only desirable and timely, but practically imperative.

There is no time when it is so important

¹Address of the chairman of the Section of Agricultural and Food Chemistry, delivered at the Baltimore meeting of the association.

to bring out correct views as to the nature of the development of an educational movement as when it is feeling some new and enormous impetus. When building progresses slowly and by stages much time is afforded for changes of plan as the work progresses, but where the progress is rapid and one stage follows another in quick succession it is of vastly greater importance that the plans shall have been fully perfected at the outset. The latter situation is certainly now before us so far as concerns agriculture and the sciences closely related thereto. The agitation for the teaching of nature study in its application to agriculture in the primary schools, the introduction of elementary agricultural instruction into the high school, the rapidly increasing demand for collegiate agricultural instruction and the imperative and almost unmet demand for university training as a proper preparation of teachers for the agricultural college and of investigators for the work of the experiment stations, have created a new and unique situation which should be met not only immediately, but most wisely. The present difficulty is not encountered solely at a single stage, but is more or less acute, as concerns the school, college and university. It is therefore of vital importance to recognize the first and most pressing need in order that by meeting it the whole situation may be relieved most quickly and satisfactorily.

The teacher of nature study in the elementary school would naturally be trained in the high school or normal school, but in this line of instruction these schools are lacking; hence there is now coming a demand upon the agricultural college to supply such teachers. The necessity under these conditions for sound instruction in the agricultural college and for men with thorough university training to teach in them, is greater than ever before.

This new demand, supplementing that for men to conduct agricultural research in the experiment stations, is creating, in turn, a demand upon the university which is to-day met only in an utterly inadequate degree; and which has forced the Association of American Agricultural Colleges and Experiment Stations to provide in a slight measure for the need, by the establishment of a short, itinerary, periodic graduate school of agriculture. It is obvious that one can no more lift himself by his boot-straps than that this entire situation can be met satisfactorily without an immediate, adequate and wisely planned agricultural educational movement emanating from the university. It must give inspiration to the college, the college to the high school and normal school, and these in turn to the elementary school teacher.

The national government is now lending its aid to collegiate training in agriculture and to agricultural research, but no adequate step has been or is now being taken in the United States to provide the funds for adequately meeting this new demand upon the university. The recent organization of the Graduate School of Applied Science at Harvard University is in line with a gradually growing movement in a number of agricultural colleges and universities.

Private munificence has been wisely lavished to provide university training in theology, medicine, pure science and law, but as regards agriculture the situation is that of neglect. It is indeed surprising that the great basic industry upon which all others depend, which would seemingly be one of the first to receive support, has been almost utterly ignored, neglected or forgotten by our wealthy philanthropists. There are also certain great agricultural research problems like respiration calorimeter studies which are so complex in their nature, so exacting as to expense and the

period of years necessary in which to reach definite results, that the experiment stations can at present hardly grapple with them, and still meet the other urgent demands which are made upon them; hence it is hoped that for such work satisfactory, permanent provision may soon be made. In this regard absolutely abstract research has been placed, through private munificence, on a far better plane. In fact this country now needs and awaits the advent of men who feel that these great problems, which by their final solution give promise of direct or indirect aid to agriculture, are also worthy of endowed support; and especially that provision for high-grade university training, in its application to agriculture, and of a pension system for experiment station research workers by which they may be placed on a par with the teachers, would be among the most fundamental, far-reaching and humanitarian projects for endowment.

Sufficient has been said to emphasize the great extent of the present movement for agricultural education and to show that somehow and from somewhere must come far greater support of highly complex agricultural research and especially of agricultural training of a university grade. Indeed, the movement from below is so general, so impulsive, and so powerful, that the situation from the standpoint of the university can not be much longer overlooked. It becomes important, therefore, to consider the place of agricultural chemistry in the university plan. In this connection it is of historic interest to recall that the American student who looked over the field of agricultural chemistry in this country twenty years ago could learn of but five or six teachers of this subject, most of whom were giving only collegiate courses of instruction which were often only partially commensurate with the university courses then offered in Germany. Indeed

it is a noteworthy fact that one of these men (Goessmann) is a German, while among the others were Atwater, Storer, Caldwell and Johnson, who had all derived their inspiration from study at German universities. Thus this country owes a debt of gratitude to Germany which may not be sufficiently appreciated; and notwithstanding the splendid agricultural chemical work done in France, England and elsewhere, Germany has long been looked upon as the mecca for the agricultural chemists of the entire world.

Such having been the case, the situation to-day is of particular interest in view of the attitude of Dr. H. Thiel, of the German Ministry of Agriculture, who at the International Congress of Agriculture at Vienna in 1907 presented and supported a scheme of agricultural education which shall entirely eliminate agricultural chemistry as such, which he designates as a "bastard" of various sciences, a subject essentially dragged in to fill a temporary gap. The effect of such powerful influence is already becoming strikingly evident in Germany, where the professorship of agricultural chemistry in certain cases, as in Göttingen and Halle, has been reduced in grade. Two other universities, Giessen and Kiel, now offer no facilities for the study of the subject under specialists. In Leipsic agricultural chemistry, formerly represented by men like Knop and Stohmann, has now been entirely banished. In certain universities the professors of agricultural chemistry are now given no seat nor vote in the faculties and no less prominent a teacher than the late Dr. Emmerling, of Kiel, was never promoted beyond the grade of "Privatdozent," and even this position has now become vacant. Fortunately at the agricultural "Hochschulen" and "Akademien" the situation is not yet so grave. Nevertheless, Professor Pfeiffer, to whose presentation of the subject I am

indebted for the foregoing facts, states that to the best of his knowledge there is not now a single "Privatdozent" in the subject of agricultural chemistry in the entire German empire, from which it would appear that in a few years, if the present policy of Director Thiel is upheld, the student of agricultural chemistry will certainly no longer look to Germany for instruction and inspiration. This view-point of Thiel's appears to be analogous to that of a former president of a purely agricultural college in the United States, who held that when botany, chemistry, physiology, geology, mineralogy, zoology, etc., had been taught, agriculture, essentially a "bastard" of these sciences, had already been taught, and hence agriculture should be utterly eliminated from the curriculum of the agricultural college. Indeed, it is hard to see, if this logic is correct, why chemists should be trained especially in the chemistry of dye-stuffs and dyeing, or indeed in any particular department of chemistry. This same view relative to agricultural chemistry appears to be held by the dean of the college of agriculture and mechanic arts of at least one large university in this country. An even more dangerous and insidious assault upon the field of agricultural chemistry is the encroachment, in the United States, of the field of agronomy, which is becoming more and more apparent with the establishment of independent chemical laboratories in such departments.

"To be, or not to be, that is the question!" Surely if agricultural chemistry has filled its little niche temporarily and has now become superfluous and useless it should be cast adrift without delay; but on the other hand it is well to consider if this is the case. No one will probably dispute that a reasonable familiarity with the whole field of organic, inorganic and physical chemistry should be prerequisite to a course in agricultural chemistry, as well as

in any other special field of technical chemistry, and that a well-trained agricultural chemist should have had fundamental training in physiological botany, physics, geology, mineralogy, general biology and other sciences. This is obvious since the investigator in agricultural chemistry is likely at any moment to be in need of the special knowledge which may be afforded him through other sciences. He may even find it desirable or necessary to associate with himself a specially trained physical chemist, bacteriologist or physiological botanist in the solution of a problem which, approached by a man trained only in any one of those lines, would be as incapable of solution as by him. If for such a cause agricultural chemistry is to be called a "bastard" science and should be eliminated from the university these other sciences deserve it equally. Instances are by no means rare where subjects have been studied from the view-point of a given science and even indeed from that side which would have been considered unquestionably the easiest and most promising line of approach, and yet it has remained for some other man approaching the subject from the point of view afforded by a remotely related science to reach the final solution of the problem. These thoughts lead to the question: Can we afford to lose the view-point afforded by agricultural chemistry, and is not the fundamental fault with it, if such fault exists, that its field has grown to be too wide? In other words, it seems probable that not less, but more, agricultural chemistry is needed in the university and in more concentrated form. In fact, a complaint was made to the writer ten years ago by one of the leading thinkers and workers in this line in Germany, that the field was already so broad, the demands so great, and the literature so voluminous, that it was becoming a mis-

taken policy in Germany to oblige a professor to cover the whole subject.

In fact, that department of agricultural chemistry which deals with animal nutrition offers by itself a sufficiently wide scope in the special chemistry of the carbohydrates, fats, proteins, gums, resins, enzymes and metabolism, involving as it does so much of the field of the physiological chemist. Presumably, from the position taken by Thiel a study of nutrition from the standpoint of the physiological chemist would be considered sufficient to meet all the necessities of agriculture. It is nevertheless absurd and hopeless to expect the physiological chemist, who approaches his subject more from the view-point of medicine or human hygiene, than of agriculture, to pursue nutrition and metabolic studies with ruminants and other farm animals, excepting in so far as the special problem is calculated to bear upon general principles or upon certain features in their relation to man. On the other hand, it can hardly be expected that the agricultural chemist will fail to concentrate his energies upon the study of these problems very largely in their relation to the nutrition of farm animals. It is important that the subject should be studied independently even notwithstanding the close relationship of the work and the fact that each at many points may touch upon the field of the other. That such close points of contact exist is no suitable argument for discontinuing the work of one or the other, but on the contrary furnishes the strongest reason for the support of each, since by this contact each receives mutual assistance.

There would also seem to be an ample field for the specialized teacher in the line of agricultural chemical technology, for example in the manufacture of fertilizers, sugar, wood pulp, alcohol, vinegar, beer, wine and the vast number of other materials which might be enumerated. In

addition, the field of the chemistry of soils, fertilizers and plant nutrition, entirely aside from the usual scope and direction of the work of the agronomist, is amply broad for one man to cover if he becomes properly familiar with the past literature of the subject, and keeps abreast of the times in connection with the many experimental and analytical features involved. The fact that this field will lead him into touch with, or even at times to encroach upon, that of the bacteriologist, physical chemist, physiological botanist or agronomist, furnishes no ground for the abolishment or restriction of one or the other, but rather emphasizes the importance of maintaining these different points of view, since they are likely at any time to furnish a special vantage ground, or new avenue for the attack upon some difficult problem, which, approached from any other direction, might not admit of solution.

The most hopeful feature connected with the teaching of agriculture in the United States at the present moment is the rapid rate at which the subject is being divided into specialties, for it is only in this way that it can ever be hoped that its students can acquire the best knowledge of the theory and practise in any given line, and no alarm need be felt if these subjects have a close "touch of elbows." When a teacher covers too large a field he is sure to be weak in his knowledge of either the theory or practise and a condition thus arises which interferes with science taking its true place in its relation to the advance of the practise of agriculture in its several departments. Indeed there is little ground for wonderment that the classically educated man who saw, a few years since, a single "professor of agriculture" struggling to cover superficially the whole of his broad field, with little if any of his subject-matter reduced to pedagogic form, should not have been moved to feel that he was merely placing a

cheap and useless veneer over the other sciences. If agricultural chemistry is today in a somewhat similar position then surely the time has come when, instead of its being thrown overboard because of its breadth, it should, like general agriculture, be properly subdivided and given the fullest opportunity for its development. It may be claimed that agricultural chemistry covers partially the same field as agronomy and hence should be eliminated; but the attempt to place such artificial barriers between the different sciences and to provide that one shall not encroach upon the field of the other prevents the greatest progress and interferes with the organization of effective and sound research. The need in such cases is provision for sympathetic and hearty cooperation. Indeed, the erection of such barriers is no less pernicious than the elimination of view-point which would come from the pursuit of pure science by itself, in the university, unaccompanied by any attempt to study and teach its application, since each furnishes a stimulus to the other. The additional point of view of the professor of applied science is too valuable to the university to be lost. It is not only vital to the welfare of agriculture and to most of our great industrial undertakings, but is helpful and even inspiring to those pursuing pure science as such.

Apparently the result of the present general movement as represented by Thiel is to remove the higher teaching and research in science as related to agriculture, entirely or largely from the universities and to concentrate it in connection with purely agricultural institutions, such for example as "Landwirtschaftliche Hochschulen." If such a general policy were adopted in this country it would mean adding to our present agricultural colleges the highest grade of university instruction in the sciences related to agriculture, rather than adding

such instruction to the university, where it could be the handmaid of pure science in its highest aspect. It is indeed possible that the former course may yet be followed in this country in consequence of the attitude of the university toward applied science, but if so, it would seem to be in consequence of following the lines of least resistance instead of adopting the wisest, broadest and most effective policy. It would seem that a divorce of science as applied to the great industry of agriculture, from the close and intimate touch with the highest and best in pure science, and from the finest academic atmosphere which the country can supply, would be an equally great misfortune to science in both its pure and applied form. In this connection, it is of the utmost importance that the college and university teacher of science, in its relation to agriculture, as well as men in training for research positions in the agricultural experiment stations, should have approached the university through an agricultural college of as high standing educationally as other institutions of collegiate grade, and that they shall not enter this university field without the close touch with agriculture and with the allied sciences which such agricultural colleges afford, since this is essential to their highest usefulness.

That which is most needed at the present time is to provide university education from the view-point of agriculture, and this ought to have immediate and splendid support.

At a time when agricultural chemistry is "under fire" it is especially fitting to consider its requirements and to judge it by its fruits. The very nature of the subject brings the teacher of agricultural chemistry in the college, and the experiment station investigator in close touch with the farmer and hence a knowledge of practical matters is indispensable to his highest success and

usefulness, a requirement which has forced from the ranks some of the general chemists who have tried to enter the field of agricultural chemistry. The conditions imposed have made the field a particularly favorable one for the young man who has been reared on the farm, who has had an agricultural college education and who is thus in position not only to give the farmer the advice and counsel which he seeks, but also to be governed by sound judgment in his scientific deductions in their bearing upon agricultural matters. The very fact that a more or less general knowledge of several sciences, and thorough training in general chemistry are required, has forced the student in this line to prepare himself more fully for his work in the past, than in many of the other sciences related to agriculture. These combined features furnish a splendid preparation for the administrative duties devolving upon the director of an agricultural experiment station. In fact it is doubtless due to these considerations that a great proportion of the agricultural experiment station directors in this country and in Europe have been chosen from the ranks of the agricultural chemists. Thus this science has yielded special fruit by way of leaders in agricultural investigation in addition to its vast number of other contributions to our general agricultural progress.

It is needless to cite what the agricultural chemist, from the time of Liebig to that of Hellriegel, has contributed to agriculture; since the men and their work are too well known and appreciated to require enumeration. It can not be disputed that without the aid of agricultural chemistry modern agricultural progress would have been impossible and the world would now be crying for food. Indeed, even a casual survey of the fruits of agricultural chemistry and of its benefactions to the people justify not only its past existence, but for

the future far greater and more general recognition in the universities, where it should receive at once magnificent support and endowment. Now is the time for us to seize upon this inheritance which Germany seems about to relinquish!

H. J. WHEELER

RHODE ISLAND AGRICULTURAL
EXPERIMENT STATION,
KINGSTON, R. I.

SCIENTIFIC NOTES AND NEWS

THE two volumes containing "The Collected Papers of Joseph, Baron Lister," will shortly be issued from the Clarendon Press. They were planned as a memorial of Lord Lister's eightieth birthday, celebrated two years ago. The committee formed for the purpose has had the advantage of Lord Lister's advice, and the two volumes contain all the papers and addresses which he considers to possess permanent value.

PROFESSOR H. F. OSBORN, of Columbia University, has recently been elected one of the twenty-five foreign members of the Zoological Society of London, and also an honorary member of the Royal Academy of Sweden, as the successor of the late Professor Albert Gaudry.

PRINCE ALBERT OF MONACO has been elected a foreign member of the Paris Academy of Sciences in succession to Lord Kelvin.

EDINBURGH UNIVERSITY has conferred the honorary degree of LL.D. on Mr. J. G. Bartholomew, hon. secretary Royal Scottish Geographical Society; Professor A. Crum Brown, F.R.S.; Professor W. Burnside, F.R.S., Royal Naval College, Greenwich; Sir Alfred Keogh, K.C.B., director-general of the Army Medical Service, and Professor C. H. Kronecker, University of Berne.

SIR RICHARD D. POWELL has been reelected president of the Royal College of Physicians of London.

DR. CLEMENS VON PIQUET, of Vienna, has been appointed physician-in-chief to the Harriet Lane Home for Invalid Children, affiliated with the Johns Hopkins Hospital and professor of pediatrics in the university.

DR. OLIVER L. FASSIG, of the U. S. Weather Bureau, Baltimore, and the Johns Hopkins University, has been placed in charge of the Porto Rican station with headquarters at San Juan.

PROFESSOR H. E. GREGORY, of the geological department of Yale University, will, on behalf of the U. S. government, undertake an expedition to the Arizona desert to seek a water supply for the Navajo Indians living on the Arizona reserve.

THE annual business meeting of the Phi Beta Kappa Alumni in New York will be held in the Hotel Savoy on the evening of May 4, when Dr. Simon Flexner, director of the Laboratories of the Rockefeller Institute for Medical Research, will address the association on the subject "The Service to Medical Science of Independent Institutions for Medical Research."

PROFESSOR JOSEPH BARRELL, of Yale University, gave a series of lectures in the department of geology at the University of Wisconsin from March 31 to April 6, dealing especially with sedimentation in some of its more modern aspects.

AT the 353d regular meeting of the Middletown Scientific Association, held in the Scott Laboratory of Physics, Wesleyan University, on April 13, Dr. Arthur Eugene Watson, assistant professor of physics in Brown University, gave an illustrated lecture on "Some Mile-stone Marks in Electrical Engineering."

A MEETING of instructors and advanced students at Harvard University for the discussion of a recent chemical research will be held in Boylston Hall at 5 o'clock on the following Thursdays: April 29, May 6, 13, 20 and 27, and June 3. The next meeting will be open to all members of the university, and the special subject will be "The Rusting of Iron," by Dr. Allerton S. Cushman, of the U. S. Department of Agriculture.

UNDER the auspices of the department of physics of Columbia University a course of lectures on "The Present State of the System of Theoretical Physics," will be given by Max Planck, Ph.D., professor of mathematical

physics in the University of Berlin, lecturer in mathematical physics in Columbia University, 1908-1909. The lectures will be given in German on Friday afternoons at 4:10, and Saturday mornings at 10:10 from April 23 to May 15.

April 23 and 24—Introduction. "Reversibility and Irreversibility."

April 30 and May 1—"Kinetic Theory of Matter."

May 7 and 8—"Radiation of Heat."

May 14 and 15—"General Dynamics. The Relativity Principle."

FRANK LEO TUFTS, B.S. (Antioch, '91), A.B. (Harvard, '94), Ph.D. (Columbia, '96), adjunct professor of physics in Columbia University and the author of valuable contributions to experimental physics, was killed by an electric shock, on April 15. He was born in Findlay, Ohio, in 1871.

DR. W. H. EDWARDS, known for his work on the butterflies of North America, died at Coalburo, West Virginia, on April 4, at the age of eighty-eight.

THE death is also announced of the Rev. Dr. Sereno E. Bishop, who had spent more than fifty years as an American missionary in the Hawaiian Islands and had made contributions to our knowledge of their volcanoes.

There will be a New York State civil service examination on May 1 for the position of assistant bacteriologist in the State Department of Health at a salary of \$1,500.

A NORTH DAKOTA ACADEMY OF SCIENCE has been organized and will hold a spring meeting at Grand Forks on May 21. At this meeting Professor M. A. Brannon will outline the work that is before the academy in the biological sciences; Dr. Geo. Stewart that in the physical sciences, and Professor D. E. Willard that in geology. The first two named are in the State University at Grand Forks and the last is in the Agricultural College at Fargo. The president of the academy is Professor H. A. Brannon, of the State University, and the secretary is L. B. McMullen, of the State Normal School.

PLANS for the Pacific Coast meeting of the American Institute of Mining Engineers pro-

vide for a visit to Yellowstone Park, September 25 to 30; Spokane, October 2 to 6; Seattle, October 8 to 11; Tacoma, October 12, and Salt Lake City, October 15 to 19. The special train is to leave New York, September 22, and return just a month later.

THE semi-annual meeting of the American Institute of Chemical Engineers will be held on June 24 and 25 at the Polytechnic Institute, Brooklyn, N. Y. The program will consist of papers, excursions and an exhibit of chemical engineering apparatus.

A CONFERENCE on public health is being held this week at the University of Illinois under the auspices of the university and the Illinois State Board of Health. Professor W. T. Sedgwick, of the Massachusetts Institute of Technology, will deliver a series of lectures on the general subject, "Science in the Service of Public Health." Dr. T. J. Bryan, chemist of the Illinois State Food Commission, will speak on "The Relation of Pure Food to Public Health." A special session of health officers will be held on April 23, for general discussion of problems of health in the state. Dr. Egan, secretary of the State Board of Health, will open this session.

DR. F. CREIGHTON WELLMAN, who has had long experience as health officer in Portuguese East Africa, gave a series of extensive lectures under the auspices of the medical department of Tulane University on the following dates and subjects:

April 12—"Insects and Human Diseases."

April 13—"Diseases of West Africa."

April 14—"A Naturalist in West Africa."

April 15—"Why the Physician in Temperate Climates should study Tropical Diseases."

April 16—"General Biological Conditions in West Africa."

April 17—"Anthropological Notes made in West Africa."

A course of eight free popular lectures was given at the Chicago Academy of Sciences on Friday evenings during February, March and April, as follows:

February 19—"The Volcano of Kilauea," by Mr. William A. Bryan, president, The Pacific Scientific Institution.

February 26—"The Deserts of Arizona," by

Dr. Henry C. Cowles, assistant professor of ecology, University of Chicago.

March 5—"Studies in Geology: The Grand Canyon of the Colorado River," by Dr. Wallace W. Atwood, secretary of the academy.

March 12—"Studies in Geology: The High Mountains of North America," by Dr. Wallace W. Atwood, secretary of the academy.

March 19—To be announced.

March 26—"The Conservation of our Natural Resources," by Mrs. Jane Perry Cook, head of department of geography, Chicago Normal School.

April 2—"Studies in Geology: The Geological History of the Chicago Region," by Dr. Wallace W. Atwood, secretary of the academy.

April 9—"Travel and Exploration in Alaska," by Dr. Wallace W. Atwood, secretary of the academy.

THE Geographic Society of Chicago has arranged for the month of May two excursions, the regular excursion on the second Saturday of the month and a special one later in the month. The regular excursion will take place on Saturday, May 15, under the leadership of Dr. Otis W. Caldwell, of the University of Chicago. The region visited will include the rich woods and the remarkable moving dunes near Furnessville, Indiana. The special excursion for May will be to Starved Rock and the Canyons of the Illinois River. Specialists will give the history of the region, explain its topography, and interpret its flora and avifauna. The society is actively supporting a measure now before the legislature looking to the incorporation and preservation of Starved Rock and its environs within the confines of a State Park.

WE learn from *Nature* that the Royal Physical Society of Edinburgh has opened its doors to women members. At the March meeting of the society, Mrs. Elizabeth Gray, Edinburgh; Miss Marion I. Newbigin, D.Sc., Edinburgh; Mrs. Ogilvie Gordon, D.Sc., Ph.D., Aberdeen, and Miss Muriel Robertson, London, were elected ordinary fellows.

THE U. S. Geological Survey has just opened at Denver a permanent branch office to facilitate the transaction of its western work, thus providing a base of supplies for the large corps of engineers who are kept in

the field many months each year, making geologic studies of mineral deposits, conducting detailed topographic surveys for the base maps of the geologic atlas of the United States, mapping the great national forests, investigating surface and underground waters, and collecting statistics of mineral production. The establishment of such a branch office is not only intended to serve the convenience of the survey corps, but it is designed also to meet the great need of the western public for a source of information less remote than Washington. A supply of copies of the publications available for free distribution will be kept on hand, as well as a complete file of the topographic maps, geologic folios, and other publications of the survey subject to sale. All of these publications will be open to inspection by persons desiring information concerning the subjects treated. Prospective purchasers of maps and folios will be referred to the nearest sales agent, and the free publications will be distributed in Denver to those making application. In short, the Denver office is intended to serve the public in all matters that lie legitimately within the province of the United States Geological Survey. The office is located in the Commonwealth Building and was opened on the first of April. R. C. Miles, special disbursing agent, is at present in charge, and will answer all inquiries, distribute documents, and maintain a visitors' register.

UNIVERSITY AND EDUCATIONAL NEWS

At the recent annual celebration of Founder's day at the University of Virginia, President Alderman announced that an endowment fund of \$1,000,000 had been completed during the past year. Between November and February \$750,000 of this total was secured in sums as follows: Andrew Carnegie, \$500,000; Oliver H. Payne, \$50,000; children of John B. Cary, \$20,000; Christian Woman's Board of Missions, \$30,000; Thomas F. Ryan, \$25,000; Charles H. Senff, \$25,000; Charles Steele, \$30,000; Robert Bacon, \$10,000; H. McK. Twombly, \$10,000; General Education Board, \$50,000. The \$500,000 given by Mr. Carnegie will become the per-

manent endowment of six existing schools in the university, and these schools are to be given the names as follows: The James Madison School of Law, the James Monroe School of International Law, the James Wilson School of Political Science and Political Economy, the Edgar Allan Poe School of English, the Andrew Carnegie School of Engineering, the Walter Reed School of Pathology.

Gifts to Princeton University for the quarter ending with the spring recess aggregated \$145,939. \$100,000 was presented by Cleveland H. Dodge, '79, of New York, for part of the endowment of Guyot Hall, the new natural science laboratory now under construction on the eastern side of the campus. A fund of \$400,000 was presented some time ago for the construction of the building, which is now nearing completion. The next largest gift came from the committee of fifty alumni who are raising funds by subscription for the immediate needs and future development of the university. This committee turned in a total of \$38,039 for the quarter, \$28,039 of which goes to current expenses and \$10,000 for endowment.

EXERCISES appropriate to the opening of the new engineering building of Rutgers College, erected at a cost of \$100,000, were held on April 14. The building contains seven classrooms, five laboratories, six professors' offices, and three draughting rooms. It is used by the departments of civil, electrical and mechanical engineering.

THE University of Pennsylvania correspondent of the New York *Evening Post* states that the cosmopolitan character of the student body at the university was emphasized at the recent formation of the Cosmopolitan Club, the object of which is to hold occasional meetings, when an opportunity will be afforded to men of all nationalities to become acquainted with each other, and to discuss matters of common interest. It is planned to hold, next year, a series of "national nights," where the customs of each country will be presented by its representatives. It was found that there are 120 stu-

dents in the university from the Latin-American countries, 50 students who are British subjects, and 31 who are Chinese. There are 32 other countries represented in the student body.

DR. A. A. MURPHREE, president of the State College for Women at Tallahassee, has been elected president of the University of Florida.

DR. R. C. HUGHES has resigned the presidency of Ripon College.

J. F. MESSENGER, A.B. (Kansas), A.M. (Harvard), Ph.D. (Columbia), professor in the department of psychology and education of the State Normal School at Farmville, Va., has been called to the University of Vermont.

M. DANGEARD, editor of the *Botaniste*, professor in the faculty of Poitiers, has been called to a chair in the faculty of sciences at Paris.

DISCUSSION AND CORRESPONDENCE

THE FUNDAMENTAL LAWS OF MATTER AND ENERGY

TO THE EDITOR OF SCIENCE: In a recent number of *The Technology Quarterly* (June, 1908) appears an article by Professor Lewis entitled "A Revision of the Fundamental Laws of Matter and Energy." It closes with the following summary:

It is postulated that the energy and momentum of a beam of radiation are due to a mass moving with the velocity of light.

From the postulate alone it is shown that the mass of a body depends upon its energy content. It is, therefore, necessary to replace that axiom of the Newtonian mechanics according to which the mass of a body is independent of its velocity by one which makes the mass increase with the kinetic energy.

Retaining all the other axioms of the Newtonian mechanics and assuming the conservation of mass, energy and momentum, a new system of mechanics is constructed.

In this system momentum is mv , kinetic energy varies between $\frac{1}{2}mv^2$ at low velocities and mc^2 at the velocity of light, while the mass of a body is a function of the velocity and becomes infinite at the velocity of light. The equation obtained agrees with the experiments of Kaufmann on the relation

between the mass of an electron and its velocity. It is, moreover, strikingly similar to the equations that have been obtained for electromagnetic mass.

The new view leads to an unusual conception of the nature of light. It offers theoretically a method of distinguishing between absolute and relative motion.

Mass is defined by Professor Lewis as momentum (M) divided by velocity (v),

$$m = M/v.$$

I should like to say a few words about this summary and the paper to which it belongs.

The notion of momentum in a beam of radiation is introduced with the aid of the "law of conservation of momentum." The other two laws required, of the three in all, are the conservation of energy and the conservation of mass.

For the sake of argument, I shall assume a beam of radiation to consist of a mass in motion and proceed to consider the use of such a hypothesis or conception.

What happens when that beam impinges on a body? That the body receives energy and that this energy is shown by the movement of the body is settled beyond doubt by experiment, but that the moving mass in the beam sticks to the body it strikes is very questionable. How can it stick to a body which radiates as much energy as it receives and of the same nature? Professor Lewis does not seem to consider this difficulty. But, for the sake of argument again, I assume that what is mass in the beam of radiation does adhere to the body it strikes. Then, of course, the mass of the body struck increases as it moves and increases as it receives this particular form of energy, but only as it receives *this particular form*. Yet Professor Lewis considers this increase of mass with energy as typical and concludes that because the mass of a body increases as it receives radiant energy, to which he assigns a very special constitution, therefore its mass increases when it receives any energy whatsoever and diminishes when it loses any energy whatsoever. Otherwise, what does the following mean:

Assuming the fundamental conservation law [of momentum? C. L. S.], we must regard mass

as a real property of a body which depends upon its state and not upon its history. Hence it is obvious that if in any other way than by radiation the body gains or loses energy, it must gain or lose mass in just the above proportion [see equation (5) below, C. L. S.]. In other words, any change in a body's content of energy is accompanied by a definite change in its mass, regardless of the nature of the process which the energy change accompanies.

This seems to me equivalent to saying that all energy is of the same nature as radiant energy, a notion not acceptable in the present state of our sciences. Professor Lewis thinks that consequently one of the axioms of Newtonian mechanics must be changed. I suppose he refers to axiom 1, but none of the three says a word about this relation. They imply this independence of mass and velocity, but were they to be found dependent, I can not see that any of the three would be changed, necessarily, in wording. I do not find in this whole development anything more than a special kind of action, one that can not be generalized at all. A ship bombarded by projectiles and moving in the same direction as the projectiles continues in the same direction as before with increased mass and increased velocity due to the mass and energy of those missiles. But who would draw any general conclusions as to the nature of all the other energies from this? It is a very easily analyzed case, but I do not see how it differs in principle from the more obscure one of radiant energy.

The change in mass for a given quantity of energy is calculated by Professor Lewis thus:

The moving mass of the beam imparts dE of energy in dt time, so in t time it imparts $(dE/dt)t$ of energy. During this time t , a quantity of energy has traveled up to the body absorbing the radiation and been delivered to it equal to fs where f is the radiation pressure and s is the distance the radiation has traveled in t time. Making t equal to unity, s becomes the velocity of radiation, V . Then,

$$f = dE/Vdt. \quad (1)$$

By condition, this f , being due to a moving

mass, imparts momentum dM in time dt and so,

$$f = dM/dt. \quad (2)$$

With (1) and (2),

$$dE/dM = V. \quad (3)$$

But a momentum from a mass dm moving with a velocity V requires that

$$Vdm = dM, \quad (4)$$

and so with (3),

$$dm = dE/V^2. \quad (5)$$

Now equation (5) is a very simple thing. It gives the mass needed at velocity V to produce the energy dE in this special way. But Professor Lewis says this equation gives the *change in mass when the energy of the body changes by dE in any manner whatsoever*. I do not see that this inference is legitimate at all.

In the fourth paragraph there is the startling statement that the mass of a moving body becomes infinite at the velocity of light. It seems to me this at once throws suspicion on the line of reasoning leading up to such a conclusion. Professor Lewis recognizes this difficulty for he says, "Therefore that which in a beam of light has mass, momentum and energy, and is traveling with the velocity of light, would have no energy, momentum or mass if it were at rest, or, indeed, if it were moving with a velocity even by the smallest fraction less than that of light," adding with great naïveté, "After this extraordinary conclusion it would at present be idle to discuss whether the same substance or thing which carries the radiation from the emitting body continues to carry it through space, or, indeed, whether there is *any substance or thing connected with the process*." (Italics mine, C. L. S.) Moreover, I do not see how this part of the fourth paragraph is consistent with (5). There is no special value, numerically, to be assigned to V in deducing (5) and so there can not be an extraordinary jump from a finite to an infinite value when V has a certain finite value assigned it. We have no right to assume that the velocity of light is the greatest

possible velocity in the universe. What would the mass become for a greater velocity? What does the mass become for the lesser velocity of light in water?

It seems to me that there is no need for any such startling conclusion. In fact, no opportunity for it, as I think will be seen from the following.

A beam of radiant energy composed of a moving mass changes the momentum of the body struck by it both by the change in velocity and by the change in mass due to the mass of the beam passing into the body struck by the beam. Hence, from the definition of momentum, $M = mv$,

$$dM = m dv + v dm. \quad (6)$$

Replacing in (4),

$$V dm = m dv + v dm,$$

or

$$dm/m = dv/(V - v).$$

In this equation, V is the velocity of the striking mass of the beam, the mass of which is dm , while v is the velocity of the object struck whose mass is m , and dv is the velocity imparted to it, to the mass m . Consequently, this equation expresses the relation between the change in mass of the object struck, due to the accretion from the mass of the beam, and v , the velocity of the object, due to the impact of the beam mass. Integrating,

$$m/m' = V/(V - v) \quad (7)$$

where m' is the mass of the object at rest, that is, when v is zero. When v is V , its mass becomes infinite, which means that a mass aggregating to an infinite mass must accumulate on the object before it will attain a velocity equal to the velocity of the pelting mass of the beam. In other words, the mass of the object must become relatively zero and not absorb any of the kinetic energy of the beam for itself, to increase its motion. This is surely simple! Who would conclude from this that when a body is given a velocity equal that of light in any way whatsoever its mass becomes infinite? Yet this is what Professor Lewis seems to do. He deduces his equation in a somewhat different way, passing through the energy and not through the momentum,

but coming out with an equation of the same nature as 7. As I understand it, he proceeds as follows:

Combining (1) and (2), for any velocity,

$$dE = v dM,$$

and replacing dM from (6) and dE from (5),

$$V^2 dm = v m dv + v^2 dm.$$

Integrating,

$$m/m^0 = V/\sqrt{V^2 - v^2}, \quad (8)$$

in which as before, when v is zero, m is m^0 , the mass of the object at rest, and when v is V , the mass is again equal to infinity, for the same reason as given previously. Professor Lewis interprets this equation thus: "According to equation (8), any body of finite mass increases in mass as it increases in velocity, and would possess infinite mass if it could be given the velocity of light."

Consider a body in a rarefied atmosphere and set in motion by the gas particles. It seems to me that Professor Lewis's reasoning will apply equally here, and then a body moving with the velocity of the gas particles should gain infinite mass. According to my interpretation of the equations, when the body did gain the velocity of the gas particles, an infinite number of them, an infinite mass, would have accumulated on the object.

I am inclined to think myself that these troubles of mine are due to unfortunate wording. If so, Professor Lewis ought to make the thing clearer, as it is very important, and I am sure many others have the same difficulty I have in harmonizing the article with one's experiences and reasoning powers.

CLARENCE L. SPEYERS

CAMBRIDGE, MASS.,

MARS AS THE ABODE OF LIFE¹

ALTHOUGH it is improbable that these lines will be read by more than a small proportion of those who have seen or heard of Mr. Percival Lowell's "Mars as the Abode of Life," it

¹ A series of lectures delivered before the Lowell Institute, Boston; later published in the *Century Magazine*, 1908; and subsequently issued as a volume by the Macmillan Company, New York, 1908.

seems worth while to point out to the scientific workers of the country the gross errors which this book is propagating. In this I shall confine myself to geological matters, leaving the astronomical and other questions to those who have special acquaintance with such things. It is not surprising that Mr. Lowell, an astronomer, should have only a layman's knowledge of geology; but that he should attempt to discuss critically the more difficult problems of that science, without, as his words show, any understanding of the great recent progress in geology, is astonishing and disastrous. One can not but recall the adage that "fools rush in where angels fear to tread."

Mr. Lowell is an implicit believer in the Laplacian theory of planetary evolution, a hypothesis now on the defensive, to say the least, and utterly abandoned by some of our best cosmogonists.

On an adjacent page he says that the minerals of the metamorphic rocks "show by their crystalline form that they cooled from a once molten state." The fallacy in this statement is evident to the average college student of geology or chemistry. Metamorphic rocks are produced by processes which involve more or less pressure and heat, but not melting.

Turning to consider the evolution of life on the earth, the author tells us that "the geologic record proves that life originated in the oceans. . . . Whether life might have generated on the land we do not know; on earth it certainly did not." The truth is that the geologic record proves nothing whatever about the origin or even the infancy of life. It may be fairly doubted whether it takes us back even to the middle age of the animal kingdom. Such a dogmatic assertion is, therefore, wholly unjustified. In this connection it is hard to resist pointing out that among the oldest known fossils are certain Eurypterids (Walcott's *Beltina danai*) which are generally interpreted as fresh-water rather than marine forms.

Farther on we read, of the plants which formed the Carboniferous coal beds, "Only a warm, humid foothold and lambent air could have given them such luxuriance and im-

pressed them with such speed." Neither Mr. Lowell nor any one else knows whether the vegetation in the Carboniferous swamps grew slowly or rapidly. We know only that they produced a certain body of coal. That may have taken a short time at a rapid rate, or a long time at the slow rate; the results would be the same. As to the warmth, it may be remarked that coal seams are now in process of growth in Alaska and Labrador and that many of the Carboniferous plants show by their structures an adaptation to severe rather than genial climatic conditions. Only a little later than the Carboniferous period most of the lands adjacent to the Indian Ocean experienced a glacial period, comparable to that of recent times in Canada; and in Australia the coal seams are interbedded with layers of glacial drift. Does this bespeak a torrid climate in middle latitudes at that time? Even the moist conditions seem to have been, as now, of local prevalence only, for aridity is indicated by the Carboniferous red beds and gypsum of Colorado and some other regions.

One of the terrestrial conditions which Mr. Lowell finds it necessary to postulate in order to bolster up his theory of Martian evolution is a perpetual cloud envelope around the earth down to about Mesozoic times—"a shady half-light" which he says is attested "by the habit of the ferns of to-day." That tree-ferns now stand out isolated on the brushy hills of equatorial Africa under the blazing tropical sun is evidently unknown to the author. Under the circumstances he would have found the services of a botanist advantageous.

With the hypothesis of a perpetually damp cloudy atmosphere we can hardly reconcile the existence of deserts in India in the Cambrian, in New York in the Silurian, in Michigan and New Brunswick in the Carboniferous, and in Germany in the Permian period. Yet the testimony of the rocks is emphatic that they did exist in those times and places.

Another of the author's preconceived opinions of Mars, which the history of our own planet has been twisted and squeezed to fit, is the shrinkage of the oceans and the eventual disappearance of water in any form. Ac-

cording to Mr. Lowell, Mars had oceans but lost them, and the earth is merely in an earlier stage of the same process. As to the earth, he says, "observation proves this to be a fact," and goes on to cite Professor Dana, who many years ago propounded the opinion that the lands had grown steadily larger from small beginnings. If Dana were alive to-day he would doubtless repudiate the idea, for it is wholly contrary to the mass of facts more recently made known. If Lowell were right, land on the continent of North America would have been smallest in the Archean and be greatest now. The truth is that there have been fluctuations of land and sea throughout recorded geologic history, and these changes show no general tendency. Just before the Cambrian period the continent was nearly all out of water; at the close of that period it was at least half submerged. At the close of the Permian it emerged more extensively than ever and yet in the Cretaceous it was again deeply inundated. Examples of the same thing could be largely multiplied, but are too well known to make that necessary.

In the face of all these facts Mr. Lowell coolly states that "wherever geologists have studied them, the strata tell the same tale," viz., the land has spread, the ocean shrunk. . . . No competent geologist would admit a word of this. Yet on this comfortable basis of fallacy Mr. Lowell then proceeds "Now, a general universal gain of the sort can mean only . . ." One is tempted to direct the author's attention to his own preface wherein he seriously admonishes that "the cogency of the conclusion hangs upon the validity of each step in the argument." The reader can judge for himself of the cogency of this particular conclusion.

Having assured his readers that the earth is drying up and that it will sooner or later "roll a parched orb through space," he cites as proof the alleged fact that deserts are increasing in size. This is the beginning of the dreadful end which "is as fatalistically sure as that to-morrow's sun will rise, unless some other catastrophe anticipate the end." Here again the proverb applies, "a little knowledge is a dangerous thing." Mr. Lowell

has seen the petrified stumps and trunks of trees in the Arizona desert and jumps to the conclusion that deserts in general have been steadily invading once forested regions, from remote ages onward. Had he inquired into the recorded facts of geologic history he would have learned that deserts have existed in many parts of the world ever since the earliest periods, wherever the topographic and atmospheric conditions were favorable. It is not probable that our present deserts are more extensive than those of the Permian period, during which the saltiest of salt lakes partially covered the site of Germany.

I think enough has been said to show what kind of pseudo-science is here being foisted upon a trusting public. "Mars as the Abode of Life" is avowedly a popular exposition of a science, not a fantasy. Its author is a highly educated man of distinguished connections and some personal fame. He writes in a vivid, convincing style, with the air of authority in the premises. The average reader naturally believes him, since he can not, without special knowledge of geology and kindred sciences, discern the fallacies. He has a right to think that things asserted as established facts are true, and that things other than facts will be stated with appropriate reservation. This is precisely the same as his right to believe that the maple syrup he buys under that label is not glucose, but is genuine. The misbranding of intellectual products is just as immoral as the misbranding of the products of manufacture. Mr. Lowell can not be censured for advancing avowed theories, however fanciful they are, for it is the privilege of the scientist; nor for making unintentional mistakes in fact, for that is eminently human. But I feel sure that the majority of scientific men will feel just indignation toward one who stamps his theories as facts; says they are proven, when they have almost no supporting data; and declares that certain things are well known, which are not even admitted to consideration by those best qualified to judge. Censure can hardly be too severe upon a man who so unscrupulously deceives the educated public, merely in order to gain a certain notoriety

and a brief, but undeserved, credence for his pet theories.

SCIENTIFIC BOOKS

L'Europe Préhistorique. Principes d'Archéologie Préhistorique. By SOPHUS MÜLLER. Translation from the Danish, by EMMANUEL PHILIPOT. Paris, J. Lamarre, Editeur. 1907. Pp. 212, text-figures 161, colored plates 3.

There was a time when civilization did not exist. When did it begin to be and whence came it? Sophus Müller believes it was transplanted into Europe from the Orient. The author has endeavored to confine his work to those elements in prehistoric archeology about which authorities are in accord.

Not much space is devoted to the paleolithic period. France is taken as a center and as the region that shows to best advantage the various stages of paleolithic culture. The reindeer epoch is lacking in Italy, as one might expect, although specimens of the Solutrean and Magdalenian types are found there.

The first epoch of the neolithic period in Italy was synchronous with the last epoch of the paleolithic period in France; the culture of middle Europe being only the periphery of a civilization more advanced in the south.

According to Müller there was in central Europe only one great period of cold after the warm climate of the Chellean epoch when man appeared for the first time. The temperature dropped during the Solutrean and became very cold in the Magdalenian, to grow milder again until the present time. He also believes the paleolithic period to be much shorter than the time ascribed to it by many geologists, notably Penck.

A chapter is devoted to the changes that came with the appearance of the neolithic period in central and northern Europe, especially the differences in the fauna and the similarities among the artifacts. The importance of Piette's discoveries of a transitional industry in the cavern of Mas d'Azil

(Ariège) is noted, as well as similar finds in northern Germany, Russia and Denmark. The north was colonized at a later epoch than were western and southern Europe, Müller placing the date at about 6000 years B.C.

The appearance of the stone ax, chipped but not polished, is what marks the beginning of the neolithic period. It was in the kitchen middens of Denmark that the two principal forms of this ax were first recognized. These shell heaps seem to have been the dwelling places of the people, as numerous hearths are found in them. Here implements were made and repaired. Sherds of a coarse pottery without ornament are also found. Two types have been determined: large jars with pointed bottom, and shallow bowls. The dog was already domesticated, but had evidently been brought to the Danish peninsula from south-eastern Europe. The stone axes of the kitchen midden types are found not only to the eastward as far as Russia, but also in southern England, over France, where it characterizes the so-called Campignian epoch, and in Italy. This is also the epoch of small arrow points with transverse edge.

But it would be an error to suppose that the civilization of the north and of the south had the same aspect. New elements were replacing the old in Italy long before they reached Denmark. On the other hand, the tardiness on the part of the latter country was an important factor in the splendid development of its local neolithic industry.

With the second stage of the neolithic period appeared the polished stone ax, a much better tool than its predecessor. It ushered in a period of general industrial development that continued uninterrupted for about 2,000 years. In the Balkan peninsula, Greece, Italy and Spain, none of the polished stone axes are of flint, although this material was used in the manufacture of other tools and arms. A striking example of this is afforded by the prehistoric station of Butmir near Sarajevo, Bosnia, where about six thousand axes and chisels were found and not one made of flint; although there was plenty of flint in the neighborhood and it was used in other forms. North of the Alps, on the contrary, polished

flint implements occur with increasing frequency until England and Scandinavia are reached. This state of things is no doubt due to the longer duration of the neolithic period in the north and to the amount of labor required to polish flint.

The art of polishing stone implements evidently originated in the Orient, as did the other characteristic element of the later neolithic, *i. e.*, the geometric ornament on the pottery that replaced the realistic art of the paleolithic. This epoch was preeminently influenced by the domestication of animals. To the dog were added the sheep, the goat, the hog and ox. Agriculture became more and more important. Wheat, barley and millet were all cultivated and all came from the Orient, as did the domestic animals. The people became less and less nomadic in their mode of life. They lived for the most part in villages composed of huts half underground. These followed one general plan—a round or oval excavation covered by a roof of branches and reeds and strengthened by the application of clay. This type of dwelling spread over Europe as far as Scandinavia and persisted for centuries. It was during this epoch that the first burials properly so-called were made. They were similar to present-day burials in that they were simple ditches sunk in the ground and were individual sepultures as opposed to the communal sepultures of the caverns; or of the dolmens of a later period. The dead were placed on the side, with arms sharply flexed at the elbows, bringing the hands to the region of the face; and the legs folded, bringing the knees near the breast. The same mode of burial was practised during the neolithic period of Egypt. Curiously enough, the same method of burial was used by the Indians of southern Connecticut before the advent of the Europeans.

Only 6,000 years is given for both the paleolithic and the neolithic period in Egypt, *i. e.*, from 10000 B.C. to 4000 B.C. For southern Europe the first epoch of the neolithic period is supposed to have begun about 5000 B.C., and the second epoch of the neolithic about 4000 B.C. These epochs began about 1,000 years later, respectively, in Scandinavia.

Copper was employed first in the Orient. It was known in Egypt as early as the first dynasty, about 5000 B.C. But its use was restricted and stone implements, particularly as cutting tools, were very generally employed until 3000 B.C. The Egyptian influence on the pre-Mycenaean civilization is noted and the characteristic stone burial cists of that epoch are described.

The beginning of the proto-Mycenaean epoch is placed at about 3000 B.C. With it appeared pottery of a new and much-improved order. The paste was fine, the modeling excellent and the ornaments in color. This epoch is known in Sicily, southern Italy and Sardinia by the sepulture *a forno*, so named because of its resemblance to an oven. Tombs of this type were communal and placed by preference in the flank of an escarpment. There also existed in these regions the dolmen proper. The two types of communal tomb are genetically related to the pre-Mycenaean stone cist. Strange to say, the dolmens spread to western Europe, Great Britain and Scandinavia, but did not replace in central Europe the ancient custom of individual burials.

The epoch of transition from the neolithic to the bronze age is called the "eneolithic" and corresponds to the Mycenaean. It was preeminently the age of the poniard, the spear and the lance coming later. Properly speaking, there was no eneolithic epoch in Scandinavia, although this epoch had a profound influence on northern civilization. For example, the flat-poled flint ax so characteristic of the north, and which is more recent than the flint ax with pointed pole, seems to have been copied after the copper axes of southern Europe at a time when metal was rare in the north and flint was plentiful. The dolmen also that characterized the eneolithic of the Mediterranean countries was introduced into Scandinavia during the first part of the neolithic period. The flint mines of Sicily and of Belgium are of the same type; but the former were worked by an eneolithic people and the process was borrowed by the races of Belgium before they emerged from a purely neolithic age. Not only flint, but also obsidian remained an article of merchandise well into the

bronze age. Obsidian is easily traceable to its original sources in Italy, Sicily and certain islands of the Aegean sea. The finest example of the diffusion of flint from a single source is that of the Grand-Pressigny (Indre-et-Loire) which is recognized by its color and has been traced not only all over France, but also into neighboring countries.

Müller enumerates the fundamental principles that should guide one in studying the relations of the central to peripheral civilizations as follows:

1. Southern Europe represented the active productive civilizing force, while the countries to the north, being peripheral, played a receptive rôle.

2. The civilization of the south was transmitted only in abridged and modified form; subject in the more remote regions to a further development along entirely new and original lines.

3. Types of tools, weapons, apparel and ornaments may persist with but little change for a considerable lapse of time.

4. Elements which along the Mediterranean belonged to successive periods may become contemporaneous in the peripheral regions.

These principles were understood by the men who founded the science of prehistoric archeology during the last century. Müller believes that Montelius would make the prehistoric epochs of the peripheral region follow too closely those of the center. He also does not agree with Penka that Scandinavia itself was a center, a source of civilization; nor with Reinach, who regards Europe as independent of the Orient.

A chapter is devoted to the closing epoch of the neolithic period in the north, where stone art reached its apogee. The finest examples are the flint poniards that are so common in the dolmens of this epoch and that have their prototype in the bronze age—poniards of southern Europe. No such development of the later neolithic is to be found in the countries bordering on the English Channel, because the development in stone art was cut short by the introduction of metal at an earlier period.

Considerable space is given to the My-

Mycean civilization which reached its zenith about 1500 B.C. It is pointed out that the dwellings of the period were not of a permanent character, while the houses of the dead were built for eternity. "The tombs with cupola of Greece and the giant dolmens of Denmark are derived from the same conceptions of life and death and are fundamentally one and the same thing. Nothing better than these monuments could reveal to us the unity of European civilization, and at the same time nothing shows more clearly the differences between the south and the north during the second millennium B.C."

Iron was known in Greece toward the close of the Mycean epoch, but was employed only for small objects. Bronze was the metal in general use. One could therefore speak of this epoch as the bronze age. But Müller prefers Mycean for Greece and bronze age for the rest of Europe, where the civilization was much less rich, though derived from the same source, i. e., from the Orient through Greece. The typical weapon of the bronze age was the poniard. The sword came later, not before the close of the period. The fibula made its appearance here and was the point of departure for the development of feminine ornament during the epochs to follow, and after having fallen into disuse for ages has only recently appeared in its original form, but with another name—safety pin.

One remarkable prehistoric phenomenon is the plentitude and decorative richness of the bronze age in Scandinavia and the mediocrity of the same civilization in western Europe. The latter was received indirectly by way of Italy, while the former came directly by way of Orient. In all western Europe from Spain to Great Britain there is not found a single fibula of the bronze-age type. This absence joined with that of the spiral ornamentation is proof that the Occident was farther removed from Greek influences than were the Baltic countries. The Mycean culture is supposed to have reached the north by way of the Adriatic, western Hungary and Bavaria.

The lake dwellings form an interesting phase of the prehistoric in Europe. They are grouped about the Alps. Switzerland, southern

Germany, Savoy, northern Italy and Austria (including Croatia and Hungary). The structures were quadrilateral, a fact suggesting Mycean influence. At least 200 village sites have been discovered in Switzerland alone since the winter of 1853-4. These belong to different epochs, the later neolithic, bronze and iron ages, respectively. Some in fact were inhabited during successive ages. The purely bronze-age stations are found farther in the water than are the purely neolithic.

Just as curious in their way as the lake dwellings are the terramaras of northern Italy. This is a corruption of "terrarnarna," a name which was given to the low flat hillocks in the valley of the Po from which a fertilizing earth has been extracted since early in the eighteenth century, long before the real significance of the deposits was known. They owed their existence to pile dwellings built on land but protected by water artificially regulated. Over a hundred have been explored thus far. The finest one is at Castione, northwest of Parma. Its present height above the plain is only three meters but the thickness of the deposit is five and a half meters. Three successive villages had stood on the spot, the first two having been destroyed by fire. The terramaras represent preeminently a bronze age culture that came from Greece by the way of southern Italy.

The Dipylon epoch in Greece witnessed the appearance of a special geometric style of decorative art, consisting of straight lines and meanders. This art, developed about 1000 B.C., was not original and spontaneous. Although it consisted of old elements, these were brought together to form a new and harmonious ensemble. The same motives were in use a thousand years later in Scandinavia. Figurines of the horse characterize this epoch. Gold and silver were scarce. The use of iron became general.

The Dipylon epoch gave Italy its first iron age, which in its turn became the point of departure for a new period of civilization in the other countries of Europe. This period in Etruria was characterized by cinerary urns of coarse paste, made without the use of the

wheel and with incised instead of painted ornaments. The motives, however, recall those of the Dipylon epoch in Greece—zig-zags, meanders, etc. All sorts of small objects were placed with the dead—among others the bronze razor with a single edge in place of the earlier two-edged razor; also, a new type of fibula with highly arched body instead of the Mycenaean type. There appeared at this time a sword with a hilt terminated by two branches—a type destined to play an important rôle north of the Alps as far as Scandinavia.

The first iron age in Italy is generally called the first Villanova epoch (1000 B.C.). It is also called the epoch of well-shaped tombs, *tomba a pozzo*. The second epoch of Villanova reveals an increasing Greek influence accompanying a local original development. Incineration gave place by degrees to interment; and ancient linear ornament was succeeded by life forms repeated in series to form zones, recalling the Dipylon style. Much progress was shown in the construction of tombs, as witness the celebrated tomb of Regulini-Galassi discovered in 1836 at Cervetri. After the fall of Carthage, Greek influence practically superseded the oriental in Etruria. After having given to Tuscany its money, alphabet, architecture, industry and divinities, Hellenic civilization crossed the Apennines and invaded the Po Valley. The best evidence of this is afforded by the Certosa cemetery at Bologna.

The first iron age of central Europe had its sources in the recent Villanovan civilization of northern Italy. It is commonly called the Hallstatt epoch, from the village of Hallstatt in Austria near which was discovered a prehistoric cemetery representing the entire period. But the Hallstatt civilization was as restricted in area as it was distinctive in character. This limited zone became a center of civilization for the contiguous countries, which for the most part were still in the bronze age. This was particularly true of Hungary, Scandinavia and Switzerland.

The second iron age, or epoch of la Tène, dating from about 500 B.C., is better known than the Hallstatt epoch. We know that

toward the close of the latter period there arose in what now corresponds to France and Germany a special civilization which reached its zenith during the fourth century B.C. There was created at the commencement of the period a decorative Celtic style of such value and refinement as to be considered not only original, but also national. Yet in the last analysis these motives are derived from the palmette and classic volute. The Celtic period may be divided into two epochs: an older corresponding to the Gallic domination and a younger represented by the discoveries at la Tène on Lake Neuchâtel. The two halves of the Celtic period were of unequal merit, the latter representing an epoch of decadence. The period left its traces in Scandinavia, some of the specimens being of excellent workmanship. In both Scandinavia and Great Britain the bronze age was prolonged into the epoch of la Tène.

The movement of civilization in western Europe during the epoch of la Tène had its counterpart in the region to the north of the Black Sea, where the cemeteries of the time have furnished such a surprising quantity of beautiful objects of art, particularly gold ornaments. This rich period may be placed between the fifth and the second centuries B.C. As one penetrates farther into the interior of Russia the indigenous Scythian art makes itself felt more and more. It is characterized by animal figurines or simply the heads of animals used ornamentally. A good part of Scythian art and industry came direct from Asia and eventually spread its influence over northern Russia and into Hungary.

Rarely has a victory had for the history of civilization such vast consequences as the victory of Alesia, 52 B.C., by which Caesar vanquished the last armies of Gaul. After this the frontier of the prehistoric domain retreated rapidly toward the north. The Germanic world came into direct contact for the first time with the classic civilization of the south.

During the epoch of invasions there was a marked development of provincial industry. The Roman bronze vases, for example, were no longer made in the south for exportation,

but in the region of the Rhine and in France. The sixteen beautiful pails from the cemetery of Hemmoor near Hanover are examples. One often finds Roman motives in use, but under forms scarcely recognizable. Among the most remarkable specimens of this kind belonging to the epoch of invasions must be classed the celebrated golden horns of Gallehus in Schleswig. To this period also belongs the Roman silver service found at Hildesheim.

Differences are pointed out between the recent Celtic civilization of Germany and that of Great Britain and Ireland. At the time the Romans gained a foothold in England local Celtic art had reached a high stage of originality and development. Celtic elements were even borrowed by the Romans, whose political domination over the land did not exercise any marked influence on the national art, which continued without interruption particularly in Scotland and Ireland, and which culminated in the heroic and legendary Celtic period of the first 500 years A.D.

The last two chapters are devoted to the closing epochs of prehistoric times in Scandinavia (500 to 1000 A.D.), and to Finland and the Slavic countries.

Müller, who is director of the National Museum of Danish Antiquities, has been known for years as a gifted writer on northern archaeology. The present volume maintains the high standard the author set for himself in earlier works. Each chapter is accompanied by a selected list of references. One misses, however, an index which is all but indispensable in a work so important as this. The next general work on prehistoric Europe will in all probability devote more space to the contributions of such men as Rutot and Penck; those of the former on pre-Chellean industry and those of the latter on the antiquity of man from the standpoint of glacial geology.

GEORGE GRANT MACCUDRY
YALE UNIVERSITY

Grundriss der Kristallographie für Studierende und zum Selbstunterricht. Von Dr. GOTTLOB LINCK. Zweite umgearbeitete Auf-

lage. Pp. 254, 604 figures, 3 colored plates. Jena, G. Fischer. 1908.

Since the appearance of the first edition of this little text-book of crystallography twelve years ago it has remained the most satisfactory elementary treatise on the subject in any language. Unlike most text-books in the same field, it discusses crystallography in all its phases. Crystals are treated as bodies possessing certain well-defined properties in consequence of their structure, rather than merely as bodies characterized by distinct forms.

Starting with a brief statement of the difference between typical fluids and typical solids, the author develops the usual conception with reference to the growth of crystals, and follows this with descriptions of different kinds of crystal aggregates, a discussion of the symmetry of crystal planes, and statements of their simplest zone relations. The 32 classes of crystal forms are then treated in detail in 92 pages. In the first edition this discussion occupied 116 pages. The reduction is due to the omission from the new edition of some unnecessary explanations of figures, to the condensation of such explanations as are retained, and to a slight rearrangement in the order of treatment of some features of the subject. Everything essential to the understanding of the principles of geometrical crystallography remains, and in addition there has been introduced a most excellent series of photographs of crystal forms and combinations that will prove a welcome novelty to the student. On the whole, the first half of the revised edition does not differ materially from the corresponding portion of the earlier edition.

It is in the last half of the volume in which the greatest changes are observed. This now occupies 114 pages as against 93 pages in the first edition. The study of the physical properties of crystallized substances has advanced so rapidly in the past decade, and the results of these studies have become of such practical importance in physical and chemical investigations that they merit much more careful consideration than is usually given them in text-books published in the English language. Indeed, there is scant reference to

this phase of crystallography in English and American text-books, and in those in which the subjects are treated at all the discussion is so poorly developed as to be practically valueless for teaching purposes.

While the elements of physical crystallography are merely touched upon in the volume under review, the development of the discussion is logical and connected, and at every step the correlation between physical and geometrical symmetry is emphasized.

The most notable advance made in this new edition, however, is in the chapter dealing with the relations between the physical properties of crystals and their chemical composition. This portion of the book now occupies 26 pages, whereas in the earlier edition it occupied only 11 pages. Morphotropism, homomorphism, isomorphism, eutropism, polymorphism and isopolymorphism are illustrated by tables of substances exhibiting these properties, and the terms are explained in sufficient detail to serve the purpose of introducing the student into the fascinating field of chemical crystallography.

In all respects the volume will serve as an excellent text-book in elementary courses in crystallography. It is more comprehensive than the usual text-book pretending to deal with the subject, as it covers the field in all its aspects. The student is shown that crystals are not merely bodies possessing characteristic forms, but that they are bodies which also possess characteristic physical properties, and that such a close relationship exists between their geometrical, their physical and their chemical properties that these characters must be regarded as being connected genetically. That crystallography is a rational science and not merely a descriptive one is the impression left by the reading of the book. It is an impression to be greatly desired of American students, who are too apt to look upon crystals from the geometrical standpoint only.

The objectionable feature of the book is its lack of references. While this omission may be argued as possibly on the whole desirable in most elementary science text-books, in a text-book on general crystallography the omis-

sion is extremely unfortunate. The literature of physical crystallography is so widely scattered that a guide to the most important articles in this branch of the subject would certainly be convenient to the user of the volume. To advanced students—and that is the class to which Dr. Linck's book will most appeal, in America at least—a guide is absolutely necessary if the study is to be followed with any seriousness. It is to be hoped that in the next edition the author will insert at least a few references which will indicate where the most important discussions in physical and chemical crystallography may be found.

W. S. BAYLEY

The Cell as the Unit of Life. By the late ALLAN MACFADYEN, M.D., B.Sc. Edited by R. TANNER HEWLETT, M.D., etc. Pp. 381 and biographical notice. London, J. and A. Churchill; Philadelphia, P. Blakiston's Son & Co. 1908. \$3.00 net.

The lectures brought together in this volume were delivered by the late Dr. Allan Macfadyen at the Royal Institution, London, during the years 1899–1902, and have been edited and published by Professor Hewlett as offering “some memento of a life full of promise and cut off all too soon.” The difficult task, undertaken *con amore*, has been well performed by the editor, and a very readable and acceptable, although from its very nature somewhat out-of-date, “introduction to biology” lies before us.

The work is divided into sections, the first of which, under the caption *The Cell as the Unit of Life*, consists of five lectures on rather elementary biology in which a captious critic might find abundant material to feed his flame; if a morphologist he would take exception to such slips as that which speaks of the “Polar Body or Centrosome” (p. 57), or if a protozoologist to false impressions given by statements such as that on page 70 to the effect that always in feeding, “the *Amaba* seeks out and selects the alga cell.” The second section, under the heading *Cellular Physiology*, is misleading in that little or nothing is said about physiology of the cell, the lec-

tures being devoted almost exclusively to fermentation and the actions of enzymes external to the cell and not intra-cellular activities. The cytologist looks here in vain for information regarding constructive and destructive metabolism, oxidation, etc., in the cell. He finds, however, an excellent and clear exposition of the kinds of ferments and of their importance in digestion in animals and plants, and in the first lecture of this second set he finds a most excellent illustration of the cost in labor of ascertaining a single scientific fact, a concise history of the development during the last two hundred years of our knowledge of fermentation being given. The third section of three lectures entitled Recent Methods and Results in Biological Inquiry, and the last section of four lectures on Toxins and Antitoxins, contain much repetition of the earlier lectures, but we find here a valuable elaboration of the lines of research in a field where Dr. Macfadyen was familiar with every inch of the ground. Here is an excellent summary of the effects of microorganisms as agents of disease and of immunity to and prevention of disease, all as understood at the time the lectures were written and well serving as a basis for those who would study the modern developments of these important lines of biological research.

G. N. C.

SCIENTIFIC JOURNALS AND ARTICLES

The Journal of Experimental Zoology, Vol. VI., No. 2 (February, 1909), contains the following papers: "Studies on Chromosomes, V., The Chromosome-groups of *Metapodius*, A Contribution to the Hypothesis of the Genetic Continuity of the Chromosomes," by Edmund B. Wilson. This contains a detailed account of the "supernumerary chromosomes," which form a specific class and vary in number in different individuals of the same species. The facts are shown to form a strong support to the general theory of the genetic continuity of the chromosomes, of which a general discussion is given. "The Effects of Desiccation on the Rotifer, *Philodina roseola*," by Merkel Henry Jacobs. The old question of the possibility of revival of rotifers after a

more or less protracted desiccation is again taken up, and as a result of numerous experiments the older view that recovery is possible after a true desiccation is confirmed and the newer one that the animal at the time of drying is protected by a water-proof cyst is shown to be based on insufficient evidence. In addition, it is shown that the process of drying serves as a stimulus to reproductive activity, a definite relation existing between the periods of drying and those of egg laying. "Protozoan Studies," by J. F. McClendon. *Amoebae* do not respond to minutely localized mechanical stimulation unless this be repeated at short intervals of time. By chemical stimulation it was found that the stimulus traveled through the *Amoeba* at a rate probably faster than the movement of the fastest ions in aqueous solution. The movement of this stimulus might be compared to the nervous impulse, save that not being confined to a nerve fiber it spreads in all directions. Experiments suggested the following hypothesis of food taking by the *Amoeba*: External chemical and physical processes cause a hardening and shrinking of the surface protoplasm, thus forming the ectosarc. Internal processes cause a liquefying of the protoplasm, thus forming the endosarc. Unstable equilibrium between these two sets of processes causes amoeboid movements. A protoplasmic food body near the *Amoeba* protects it locally from external processes and thus causes the *Amoeba* to bulge out toward the food. That spot on the *Amoeba* that touches the food is stimulated, hardens and ceases to advance. Therefore lateral pseudopodia are formed and surround the food. *Paramecia* were centrifuged for periods of time up to one week. The nuclei, chromatin and other heavy substances were precipitated, but returned to their normal positions in about the length of time during which they had been centrifuged. The negative geotropism returned simultaneously with return of these substances. Centrifuging stimulated division. Centrifuging produced abnormalities and these were not transmitted to both products of binary fission. *Paramecium aurelia* formed membranous cysts and while in them often absorbed its own anterior or

posterior end. These were regenerated after liberation. The encysted *Paramecia* were killed by drying. From material obtained from a number of localities *Paramecium aurelia* was found to be dimorphic as regards size and the smallest specimens smaller than the smallest of *Paramecium caudatum*. "The Artificial Production and Development of One-eyed Monsters," by Charles R. Stockard. Salts of magnesium in solution are found to cause one-eyed monsters to develop from the eggs of the fish, *Fundulus heteroclitus*. These cyclopean individuals were produced in such numbers as to afford material for a full investigation of the processes involved in the formation of the defect.

BOTANICAL NOTES

VEGETATION PICTURES

SOME years ago Professors Karsten and Schenck, the former of the University of Bonn, and the latter of the Technical High School of Darmstadt, began the publication, through Gustav Fischer, of Jena, of a most interesting work under the title of "Vegetationsbilder." From time to time the successive parts have been noticed favorably in these columns, and now the reception of "Heften" 1 and 2 of the seventh volume calls for another notice. These are devoted to the vegetation of the volcanic regions of Java and Sumatra, and were prepared by Professor A. Ernst, of the University of Zurich, and the seventeen half-tone plates were made from photographs taken by him also. These plates are admirable examples of what may be done in the way of faithful reproduction, and make one wonder why it is so difficult, or perhaps even impossible, to secure work of this kind in this country at anything less than prohibitive prices. It is difficult to single out from these striking pictures those of greatest interest, but No. 6a showing pioneer vegetation on the volcano Merapi (2,981 meters), and No. 11a showing a grass steppe in the interior of the volcano Krakatau are especially noticeable. The text, of which there are twenty-four pages, is full and satisfactory. The excellence of the work, together with its

very moderate price (2.50 Marks per heft) should make it one of the necessary works in every botanical library.

ANOTHER BOTANICAL JOURNAL

ON the first of January the well-known publisher, Gustav Fischer, of Jena, began the publication of a promising new monthly journal in the botanical field under the name *Zeitschrift für Botanik*. In size of page and number of pages for each number it resembles the *Botanical Gazette*, which in these respects was frankly taken by the projectors as the model for the new journal. The editors are Oltmanns, Solms-Laubach (who now withdrew from the *Botanische Zeitung*) and Jost, which fact is a guarantee of the high grade of the journal. This initial number consists of three parts, viz., (1) an original article of 86 pages; (2) reviews, covering 16 pages, and (3) a classified list of titles of new botanical books and papers. In the first paper there are 26 cuts, but this number contains no plates. The type and paper are good. The subscription price is fixed at 24 Marks. It will without doubt soon prove to be one of the most useful of the German botanical journals.

AMENDING THE VIENNA CODE

IN the February number of the *Bulletin of the Torrey Botanical Club* nineteen American botanists print eleven motions for amendments to the Vienna Code, and present arguments therefor. These motions are submitted "for the consideration of the International Botanical Congress to be held in Brussels in 1910." Briefly these motions cover the following points:

1 and 2. To apply these rules to fossil plants and non-vascular plants, which is not now done in the code. These appear to be desirable motions, and should be adopted.

3. To abolish the list of "Nomina conservanda," i. e., names arbitrarily conserved contrary to the principle of priority. Here the contention of the committee is sound, and ultimately the code must be so amended as to conform to it, but whether this should be insisted upon at the present time admits of argument.

4 and 5. To change the rule requiring Latin diagnoses, to "Latin, French, English or German." The rule as adopted in Vienna is better, in our opinion, than the proposed modification.

6. To more clearly indicate valid and invalid naming of genera and higher groups. Here the committee's proposed amendments certainly make the rule more definite.

7. To provide for the disposition of the species when a genus is divided into two or more genera. Here again the committee's recommendation is much more specific than the rule in the code, and seems to provide for all the cases that may come up under it, which the original rule does not.

8. To provide for the proper retention of the original name in the division of a species. The committee's rule is much more specific and is a marked improvement upon the rule in the code.

9. To provide that priority of place upon the page shall be actual priority in the case of simultaneous publication of names. This is so reasonable that it should meet with no opposition.

10. To provide for the rejection of certain names by a more definite indication of the cases. The committee would reject "homonyms," "metonyms," "typonyms" and "hyponyms." Their statement is better than that of the code and may well be adopted by the congress.

11. To allow the specific name to be the same as the generic name, as in the familiar cases of *Taraxacum taraxacum*, *Linaria linaria*, etc. The Vienna Code requires the rejection of the specific name in such cases, in spite of the law of priority. The committee very properly regard this as "an unfortunate exception to the general law of priority."

On the whole it seems that this committee of American botanists is warranted in presenting its motions for amendments. With the exception of the fourth and fifth, relating to the diagnoses of new groups, we hope that these motions for amendments will be adopted.

A DISCUSSION OF SOME OF THE PRINCIPLES GOVERNING THE INTERPRETATION OF PRE-PER-SOONIAN NAMES, AND THEIR BEARING ON THE SELECTION OF A STARTING-POINT FOR MYCOLOGICAL NOMENCLATURE¹

If there is any one fact which more than others has become increasingly evident during the last thirty years in the study of fungi it is that a thorough examination of their microscopic characters is necessary for the certain determination of most of the species. The older systematists based their species entirely upon external characters. While the spores of fungi were early observed, they were regarded as of no importance systematically, and even as late as 1849 Fries himself forcibly stated that in the whole family of Discomycetes no natural genera could be based on carpological characters. In the decade between 1860 and 1870, however, influenced by the work of the Tulasne brothers and of de Bary, systematists turned their attention more seriously to the study of microscopic characters, and it at once became evident that important diagnostic marks were to be found in structures too small to be seen with the unaided eye. The great amount of careful morphological and developmental work which has been done among the fungi during the last thirty-five years has only emphasized the importance which should be attached to microscopic characters in distinguishing genera and species in this group. To such lengths has this tendency developed that in recent years whole systems of classification have been proposed based almost entirely on microscopic features, and in the eyes of all workers such characters have come to be regarded as the most important available bases for generic and specific distinction.

This method of study has frequently developed the fact that two or more plants, externally indistinguishable, really represented as many different species or even distinct genera. Illustrations of this condition are

¹A paper read before the Botanical Society of America at its meeting in Baltimore, December 31, 1908.

very numerous among the Ascomycetes, and will at once occur to any one at all familiar with the fungi. A few concrete examples will perhaps put the matter in a more definite light. The genera and species of the Phycomycetes are based almost entirely on microscopic characters. Among the powdery mildews the genera *Sphaerotheca* and *Erysiphe*, as well as *Podosphæra* and *Microsphæra*, can not be distinguished from each other without the use of the microscope. Most of the genera and species of the Pyrenomycetes are founded on characters drawn from the asci and spores, which can not be made out with the unaided eye. Among the Discomycetes the genus *Trichoglossum* is represented in America by about half a dozen species which are indistinguishable by their gross features. The genera *Geoglossum* and *Corynetes* can not be told apart by external characters. The same is true of *Barlæa* and *Humaria*, *Sphærospora* and *Lachnea*, and many others. In nearly all of these genera are whole groups of well marked species which are based entirely on minute microscopic characters. Specific limits among the rusts, smuts and other groups are too familiar to need mention. On the other hand, it is equally true that there are certain fungi which are so unique and well marked that they stand off by themselves, and can be much more certainly recognized by external features alone. Such species occur more commonly among the larger fleshy and woody forms, but even here minute hymenial characters are recognized as being of the greatest systematic importance. No one can venture to assert that careful students of these better marked forms may not soon discover microscopic features at present unused which may entirely upset our ideas of their specific limits. It is not necessary to dwell further on this phase of the subject, for the facts are too familiar to need elaboration. Enough has been pointed out to emphasize the fact that the number of species of fungi which may be placed with certainty on the basis of external characters alone is comparatively small.

If, therefore, the accurate determination of most of the species of fungi on the basis of gross characters alone is next to impossible

when the living plant is actually before one, how much more uncertain must be the identification of the species of older writers, which are represented by only brief descriptions of the most obvious external features, or at best by figures often crudely drawn or inaccurately colored. The simple fact is that the majority of the species of fungi described by writers before 1800 can not be recognized with certainty at the present time, when measured according to present-day standards. Yet systematic literature is filled with the references of well known fungi to names dating from Linnæus, Scopoli, Jacquin, Batsch, Bulliard, Paulet, Schaeffer, Adanson, Schrader and many others, the majority of which are at best involved in doubt. Of course it is perfectly possible for one to speculate on the probabilities in such cases, but positive conclusions can never be inferred from doubtful premises, and he will be no nearer definite knowledge at the end of his speculations. The writer firmly believes that in the field of systematic mycology a single gram of knowledge is of more value than kilos of guess-work, supposition and uncertainty, and he wishes here to raise the question and to invite discussion as to whether the time has not come to take steps to eliminate from consideration these old names, the great majority of which can never be definitely fixed.

We are thus led naturally to inquire Why should mycological nomenclature date from Linnæus's "Species Plantarum" of 1753, and thus include this mass of undeterminable names? While Linnæus had a good understanding of vascular plants the distinguishing characters of which are gross and external, his knowledge of the lower organisms, especially of algæ and fungi, was very slight. Indeed, it seems probable that very little that he wrote concerning the fungi was based on his own first-hand knowledge, but that his work with these plants consisted principally in the application of binomial designations and brief descriptions to those figured by his predecessors. The distinguished botanists of Harvard University have stated the matter so admirably that I can do no better than to quote from them as follows:

Although the year 1753 seems eminently desirable as the starting point for the nomenclature of the spermatophytes, the use of this date among the lower groups, as for instance the algæ, appears not only highly inexpedient but well-nigh farcical. Among the flowering plants both genera and species had by 1753 been interpreted with a tolerable degree of definiteness, and their descriptions were at that time drawn with sufficient understanding of morphological and diagnostic features to make them in general intelligible to future generations. On the other hand, at the date of Linnaeus's "*Species Plantarum*" the knowledge of the algæ was far too crude to form a satisfactory basis for their classification or nomenclature. Even the optical appliances necessary for the intelligent examination of this group had not been invented. What is here said of the algæ is quite as true of the fungi and applies in lesser degree even to the bryophytes and pteridophytes. Furthermore, the great difficulty or impossibility of preserving specimens in several of the lower groups, and the consequent fact that no type specimens are now extant for a large proportion of the species of the lower orders, render it all the more imperative that the beginning of nomenclature in these groups should not be carried back to a time of brief, vague and unintelligent descriptions.

In consideration of these facts it seems desirable that in the nomenclature of the spermatophytes priority should be reckoned from the publication of Linnaeus's "*Species Plantarum*" in 1753, but in the case of all other groups, from a date near 1800, to be more exactly determined by a committee of specialists in cryptogamic botany, appointed by the International Congress in whatever manner it may seem best.*

Acting with a knowledge of the facts so comprehensively stated in the quotation just given certain algologists are advocating the selection of much more recent dates as the points of departure for the nomenclature of certain groups. Why should not students of the fungi do the same; and, if any such action is to be taken, what is the most desirable date to be selected? The writer has seen only a single definite proposition bearing on the selection of such a starting-point, and ventures to offer the following suggestions in the hope that they may stimulate discussion of the matter.

* "Amendments to the Paris Code of Botanical Nomenclature," p. 13, 1904.

It may be well to point out at once some of the considerations which should have weight in the selection of a starting-point for mycological nomenclature. In the first place there should be, if possible, a common point of departure for all groups of fungi. Secondly, the date selected should be early enough to include the greatest possible number of published names. Thirdly, it should, if possible, mark the beginning of some important epoch in mycological history. Fourthly, the personage whose work is chosen should be one of the most prominent in the development of systematic mycology. Fifthly, the specific work selected should be a comprehensive one which deals with all the principal groups, which summarizes what has been done before, and which, in a word, bears about the same relation to the classification of fungi that Linnaeus's "*Species Plantarum*" does to that of the vascular plants. Sixthly, and perhaps most important, it should be the work of a person who preserved a considerable proportion of the specimens on which his publications were based, and whose collection is now available for examination, so that his names can be fixed with some degree of definiteness.

It would be too much to expect that any one work should be in all respects ideal, and it would be impossible to select one which would not be open to some objection, but the one which in the opinion of the writer comes the nearest to fulfilling all the requirements named above is Persoon's "*Synopsis Methodica Fungorum*," published in 1801.

A brief historical sketch will make clearer the reasons for this opinion. The development of systematic mycology covers three quite distinct periods, each of which is marked by its own peculiar point of view and characteristic method of work. These may be designated as (1) the pre-Persoonian period or period of the illustrators, (2) the Persoon-Friesian period or period of the systematists, and (3) the modern period or period of the morphologists. The first period covers approximately the last three quarters of the eighteenth century, extending from about 1725 to about 1800, and as characteristic may

be cited the work done by Vaillant, Micheli, Schmidel, Schaeffer, Batsch, Holmskjöld, Bulliard, Paulet and Sowerby. These men were all essentially illustrators. In their publications the larger and more conspicuous fungi were figured with some care and usually in color. Their plates were accompanied by descriptive text which, of course, dealt only with the gross and external features of the plants discussed. In most cases names were applied to the plants illustrated. Before the time of Linnæus these were mostly descriptive polynomials, but later the binomial method of designation was employed. Although the illustrators came to group their species in several genera on the basis of the most obvious superficial resemblances, no attempts were made by any of them to perfect a systematic arrangement of the fungi which could be at all compared with those which had been worked out for the flowering plants during the same time. In only a few instances have any of the fungi illustrated in this period been preserved so that aside from the information conveyed by the descriptions and figures we have no means of determining what plants the authors had before them. The writer has already attempted to show that the majority of the species of fungi described in this period can not be recognized with certainty at the present time, when measured according to present-day standards. The information about fungi in this period was in a much more crude and unsystematized state than that which prevailed concerning the spermatophytes before the time of Linnæus. It is primarily of historical rather than scientific interest, and consequently can be left out of consideration without any resulting serious loss to scientific knowledge. Surely no logical starting-point for mycological nomenclature can be found in this archaic period.

The second period of mycological history covers approximately the first two thirds of the nineteenth century, extending from 1800 to about 1865. With the advent of Persoon a complete change came over the aspect of mycological study. The attention of workers was turned from the illustration of fungi to their classification and systematic arrangement.

The work of this strange man in his garret at Paris either directly or indirectly profoundly influenced that of such students as Wahlenberg, Fries, Schumacher, Nees von Esenbeck, Corda, Ditmar, Rabenhorst, Schweinitz, Duby, Desmazières, Leveillé, Montagne, de Notaris, Berkeley, Broome and many others who came after him, and whose names are familiar as household words to the mycologist. As the result of their labors immense numbers of new species were brought to light, their external features described, and arranged according to the then approved systems of classification. This method of work characterized the second or Persoon-Friesian period of mycological development.

While Persoon's publications before 1800 were of minor extent, yet they introduced an entirely new point of view. Persoon really originated systematic mycology. The "*Synopsis Methodica Fungorum*," of 1801, is one of the few epoch-making mycological publications. Not only was it the pioneer work of its kind, but it became the direct foundation of the Friesian system of arrangement which remained in almost universal use for half a century. While the Persoon-Friesian methods of classification are not those in use today, they were probably the best which the existing knowledge of fungi permitted, and they undoubtedly served their purpose fully as well as did the Linnæan system among the seed-plants.

Persoon's "*Synopsis*" was a comprehensive work in that all the groups of fungi known at the time were treated. It was synoptical in that its author went over the works of his predecessors, brought together the scattered descriptions, and either incorporated the names directly or arranged them as synonyms as seemed to him warranted by the evidence at his command. The "*Synopsis Methodica Fungorum*" therefore bears about the same relation to the systematic arrangement of the fungi that Linnæus's "*Species Plantarum*" does to that of the spermatophytes. The same reasons which led to the adoption of the latter as the starting-point for the nomenclature of the higher plants should cause Persoon's work to be chosen for that of the fungi.

While it is true that Persoon, and nearly all the students of fungi in this period, studied only external characters, it is equally true that Persoon and Fries and the majority of the workers of their time *preserved a considerable number of their fungi*, and their collections are now available for study. The result is that a majority of the names from Persoon down can be fixed with a degree of definiteness which is impossible for those described before his time. Objection may be raised that many of Persoon's types are missing from his herbarium; that herbarium specimens are liable to become interchanged, and that in other cases it is often difficult or impossible to determine just what his type of a particular species was. There is undoubtedly force in this argument, but it must be admitted that specimens, although sometimes confused, are the most reliable bases for determination that we have, and the same objections may be brought against any other collection, even against some of those of quite recent date.

Some mycologists, perhaps, might be willing to begin their nomenclature with Persoon, but would urge that his more mature and elaborate work, the "*Mycologia Europæa*," should be chosen as the starting-point. To the mind of the writer the principal objections to starting with this later work are: (1) That its publication extended over several years, from 1822 to 1828; (2) that it was almost exactly contemporaneous with another equally, if not more important work, the "*Systema Mycologicum*" of Fries; (3) it, therefore, does not stand out in a class by itself at the beginning of an epoch.

It has been suggested by certain students of fungi that the "*Systema Mycologicum*" of Fries should be used as the starting-point for mycological nomenclature. While the writer recognizes fully that this work is one of the most important and influential systematic mycological contributions yet produced, and that scientifically it was a great advance upon the "*Synopsis Methodica Fungorum*" of Persoon, yet he believes that no lack of appreciation of its value is shown in the conviction that it is not so natural a starting-point for

nomenclature as is Persoon's work. The following reasons may be given in support of this opinion: (1) The publication of the "*Systema*" extended over several years from 1821 to 1832, a long period of time which would, in fact, establish different starting-points for the various groups of fungi. (2) In the year of publication of each of the earlier parts appeared important works by other authors (*e. g.*, S. F. Gray, 1821; Persoon, 1822; Schweinitz, 1822; Greville, 1823), in which cases it would be difficult if not impossible to determine priority of publication. (3) It, therefore, does not stand out in a class by itself at the beginning of an epoch, but is one of a number of publications on the same subject which appeared about the same time. (4) While Fries's system of classification was much more elaborate than that of Persoon, and showed a better understanding of relationships and of the relative value of characters, it was in many, if not most, of the groups founded directly upon that in Persoon's "*Synopsis*." (5) Fries's species are no more capable of positive identification at the present time than are those of Persoon.

The third period in the development of mycology began in the decade between 1860 and 1870, when the second and most important change came over the aspect of the study of fungi. This movement was inaugurated by the publication of the Tulane's "*Selecta Fungorum Carpologia*" (1861-1865) and of de Bary's "*Morphologie und Physiologie der Pilze, Flechten und Myxomyceten*" (1866). Most of the work done before this time had consisted in the almost interminable species-making on the basis of the external and gross features of the plants examined, but from this time on the attention of students was directed to the study of the morphological details and the development of fungi, a kind of investigation which has laid the foundation for sounder systems of classification. In some respects it would be better to start the nomenclature of fungi with some important work in which the

* For a concrete example see the present author's analysis of the relation of Fries's classification of the fleshy discomycetes to that of Persoon in *Bull. Torr. Bot. Club*, 27: 464-466, 1900.

more modern ideas of classification are made use of. There is, however, no great epoch-making work in this period which is adapted to being made such a starting-point, and, moreover, the selection of such a late date would exclude a very large proportion of the known genera and species of fungi, which had been described before the period began.

The question will naturally arise in the minds of some. Why, after all, is it necessary to fix a special date for the beginning of nomenclature of the fungi? It is manifestly impossible to adopt any starting-point which will effectually remove from consideration all the vague and uncertain names. Why not leave the matter open? Let monographers trace the history of each species and adopt the earliest name which can with certainty be applied to it, and relegate the uncertain names to the limbo of species *ignotæ*. One may reply to such objections that the whole matter is one of expediency; that while many of the names published after 1801 must always remain undeterminable on account of the absence of authentic specimens, the majority can be definitely identified because the describers preserved the specimens on which the names were based; that while some of the names published before 1801 were applied to plants so unique that they can be placed with reasonable certainty without specimens, the majority can never be accurately, or even approximately, determined for the reasons already pointed out; that as long as the way remains open attempts will be made continually (as has been done in the past) to revive these archaic names on the basis of supposition and a discussion of the probabilities in each case, a kind of reasoning which can never lead to definite conclusions, but which must always be productive of uncertainty and difference of opinion, with a consequent continued unsettled condition of the nomenclature of even the commonest fungi. For these reasons the writer believes that a special starting-point should be adopted so that a large proportion of these vague, indefinite, unintelligently characterized names which can never be definitely fixed should be effectually disposed of.

The writer would, therefore, urge the

adoption of Persoon's "*Synopsis Methodica Fungorum*," of 1801, as the starting-point for mycological nomenclature for the following reasons:

1. The names applied to fungi before the time of Persoon should be excluded from consideration for the reason that the majority of them can never be definitely and certainly identified.

2. Any publication in the modern period is too recent and exclusive, a large proportion of the systematic work with fungi having been done before it began.

3. Its date of publication is early enough to include a great majority of the published names of fungi, and nearly all of those which can be certainly fixed at the present time.

4. Its publication marks the beginning of the second important epoch in mycological history, that of the scientific study of fungi.

5. It is the first important systematic work of the founder of systematic mycology, and is therefore the logical point with which to begin the nomenclature of the subject.

6. It is a comprehensive work which can be used as well as any other as the common point of departure for all groups of fungi.

7. It is a synoptical work which summarizes what had been done before its time, so that it bears about the same relation to the classification of fungi that the "*Species Plantarum*" of Linnaeus does to that of the seed-plants.

8. Persoon's herbarium is in existence and is available for study, so that a considerable proportion of his names can be fixed with a degree of definiteness which is impossible for those published before his time.

9. It possesses an advantage over the "*Systema Mycologicum*" of Fries in that it was published within the limits of a single year in which no other important work on mycology appeared, so that it stands alone in a class by itself at the beginning of an epoch.

10. The adoption of this date would remove the incentive for much guess-work and speculation on the probable identity of many of the vaguely and unintelligently described or crudely figured species of fungi, which must always remain incapable of certain identifica-

tion, and would thus contribute materially to the stability of mycological nomenclature.

ELIAS J. DURAND

BOTANICAL DEPARTMENT,
CORNELL UNIVERSITY

SOCIETIES AND ACADEMIES

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 456th meeting was held March 6, 1909, with President Palmer in the chair. Dr. Theodore Gill offered some notes on oral gestation in cichlid fishes. He said that there was much to learn about the habits of American cichlids and especially about their buccal incubation. Professor Putnam as long ago as 1863, in the *Proceedings* of the Boston Society of Natural History (p. 226), remarked that "in the genus *Bagrus* [really *Arius*] Professor Wyman found that it was the male that took charge of the eggs, while in the Chromoids [i. e., Cichlids] it is the female. The specimens in which this peculiar fact was noticed were presented to the Museum of Comparative Zoology by Rev. J. C. Fletcher, from the Rio Negro, and by Professor Wyman, from Surinam. In these specimens the eggs and young were found in all stages of development."

This statement has been universally overlooked and various authors, especially Lortet and Günther, maintained that it was the male that took charge of the eggs, and not till 1902 and later did Boulenger and Pellegrin demonstrate that it was always the female of Syrian and African cichlids that did so. There was much uncertainty about the American species and the genus comprising the "two species" observed by Putnam was not named. It was probably *Geophagus*.

Very recently, in an article on the "Freshwater Fishes of French Guiana" extracted from the *Revue Coloniale*, Dr. Pellegrin claimed that it was the male of the American *Geophagi* that nurses the eggs; his words are "Chez les Géophages américains c'est le mâle qui se charge ainsi des soins à donner aux œufs et aux jeunes; chez les Cichlides africains comme les Tilapies, c'est la femelle ainsi que M. Boulenger et moi l'avons montré."

It is improbable that the American species differ so decidedly from the African and the neglected half-century-old observations of Wyman and Putnam deserve resurrection. Perhaps the specimens observed are still in the Museum of Comparative Zoology and can be identified by Mr. Garman or Professor Eigenmann. Agassiz in his "Journey to Brazil" in 1865 made some

observations but did not state whether the egg-carrying individuals were females or males.

Now that much attention is being paid to the breeding habits of fishes, we may hope that definite observations will soon be made of American cichlids. Some, indeed, have been published by German aquarists which appear to show that there may be considerable difference in the habits of the species, but the information is still unsatisfactory. May this note serve to elicit more definite data.

Dr. L. O. Howard referred to the importation of the brown tail moth accompanying seedlings from France. It is a practise of American nurserymen to buy seedlings from the north of France. Thirty per cent. of a recent shipment carried the winter nests of the moth. There is no national inspection law in this country and the stock had become widely distributed before its infection was known. Much of it was later traced and destroyed under state laws. An old federal law forbids the carrying of such infected stock in vessels, and steamship companies after a warning are now more careful in this respect. A protest from the French nurserymen alleged that the brown tail moth would not thrive in our northern states, and was already common in the southern states. But the fact is that in this country the moth is a great pest in the northern states to which it is confined.

The chair referred to the reservation by executive proclamation under the Monuments Act of several regions containing objects of scientific interest. The recent creation by President Roosevelt of the Mt. Olympus National Monument in the Olympic Mountains of Washington, the home of the Roosevelt elk, is the first of its kind having a zoological as well as geological interest.

Dr. Evemann called attention to a recent act of Congress which provides for the establishment of a biological station at Fairport, Iowa. An appropriation of \$25,000 for the establishment of this station was made a year ago and recently Congress passed the item providing for the personnel. The site has been definitely selected at Fairport, Iowa, where the bureau has acquired sixty acres of land admirably suited to the purpose. About fifty acres of the land lies along the river front and is exceedingly well adapted to the construction of the necessary ponds, of which there will be several acres. Near the river front is a railroad used by two companies with a number of trains each way daily, thus affording adequate railroad facilities. Some 1,800 feet from the river front is a public highway connecting

Muscatine and Davenport. Just above the highway the ground rises into a low bluff near the base of which are beautiful locations for the director's residence and such other residences as may be required. The laboratory proper will doubtless be located on the lower land just below the public highway.

It is the intention of the Bureau of Fisheries to make this in every respect a well equipped biological laboratory where any and all problems concerning the aquatic life of the streams and lakes of the upper Mississippi Valley may be studied. The primary and most important purpose of the station will be the carrying on of experiments and actual culture in connection with the artificial propagation of the Unionidae or fresh-water mussels. The shells of various species of fresh-water mussels are now being used extensively in the manufacture of pearl buttons. The industry centers at Muscatine and Davenport, between which two cities the biological station will be located. The business now utilizes more than 50,000 tons of these shells and produces an output of \$6,000,000 worth of buttons and by-products annually. Naturally this heavy drain upon the supply of shells will soon lead to the depletion of the beds unless something can be done toward the artificial propagation of the species. Drs. Lefevre and Curtis, of the University of Missouri, have fortunately developed, purely through scientific investigation, methods by which several of the species can be propagated very successfully, and it is the intention to carry on mussel-cultural work of this kind very extensively at the Fairport station.

In addition, however, to the mussel-cultural work, it is the intention to equip this laboratory in such a way as to furnish adequate facilities for the study of the various species of fishes and other aquatic animals and aquatic plants of the upper Mississippi basin, and it is believed that this will appeal to the biologist of that region as well as of the entire country.

The personnel provided consists of (a) director, (b) superintendent of fish-culture, (c) two scientific assistants, (d) one shell expert, (e) one engineer, (f) two firemen and (g) two laborers. Construction work on the station will begin early in July and it is hoped that the station may be ready for work by November.

The following communications were presented:

Chickens without Feathers: R. H. CHAPMAN.

Illustrations were shown of fowls that had failed in normal feather development. The birds were

observed at Delhi, N. Y., during the summer of 1908. About 500 chicks of the barred Plymouth Rock variety were incubator hatched during June. They were all apparently normal for a short time, but about ten per cent. failed to grow the usual covering. The photographs shown were taken in November and the birds were about four months old, and included the fully feathered as well as naked birds. The death rate among the freaks was high, though some of them lived until the cold weather set in. The only clew to an explanation given was the fact that the parents of the chicks had been persistently inbred for some four years. The phenomenon has been previously observed at farms in Virginia but never in such a large proportion of the hatching.

Résumé of a Study of the Madreporaria of the Hawaiian Islands: T. WAYLAND VAUGHAN.

The Recent Crinoids and their Relation to Sea and Land: A. H. CLARK.

The speaker discussed the distribution, ecology and coloration of the recent crinoids, following closely his paper on the subject published in the *Geographical Journal* (London) for December, 1908; he said further that the predominating purple or violet in the littoral species may be a factor of great importance in their economy, for many of the small organisms upon which they feed are strongly attracted by the violet rays of the spectrum, and hence would tend to swim toward a purple or violet crinoid, placing the latter in the economically advantageous attitude of attracting to itself, instead of having to pursue its food. *Uintacrinus* was cited as an instance of a purely pelagic derivative from the common comatulid stock; in life it probably floated with its globular body upward and its arms dependent downward, just like the similarly built jelly-fish of recent seas; it lived in great masses, as do many recent medusae, and this was probably an advantage, for these masses would shade the water immediately beneath them, and many of the small lucifugous organisms would take refuge in this shade, only to be picked up and eaten by the *Uintacrinus*. The occurrence of crinoids in large masses of individuals all of which are of approximately the same size was explained by the inability of the young of the mass to obtain a food supply when shaded by the arms of the adults; hence the young can not survive unless drifted to some distance from the parents.

The 457th meeting was held March 20, 1909, with President Palmer in the chair. The program consisted of an illustrated discussion of "Camp-

ing and Camp Outfits," by A. S. Hitchcock, V. Bailey, H. S. Barber, W. H. Osgood, J. W. Gidley and E. A. Preble. Articles of camp equipment were exhibited, methods of carrying packs demonstrated, and many lantern slides shown.

M. C. MARSH,
Recording Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 663d meeting was held March 27, 1909, Vice-president Wead in the chair. Two papers were read.

The Present Status of Wireless Telegraphy and Telephony: Dr. L. W. AUSTIN, of the Bureau of Standards.

Two years ago there were four principal practical problems before the workers in radio-telegraphy:

1. Doing away with the irregularities of the atmospheric absorption of the signals which caused waves of the same intensity to be at one time detected at a distance of 1,000 miles, at another not over 100.

2. The elimination of the disturbances in the receiving station due to atmospheric discharges which frequently made the reception of signals entirely impossible.

3. The production of directed signals capable of commercial use.

4. The production of electrical oscillations suitable for wireless telephony.

The first of these problems has been successfully attacked by Professor Fessenden, who has shown that by using a wave-length of approximately 4,000 meters the absorption is much reduced and becomes practically constant under all conditions both by day and night.

The second problem is still not satisfactorily solved, although the conditions are much improved by sharper tuning of the receiving circuits and especially by the use of a loose coupling of the receiver.

In regard to the third problem, a certain amount of success has attended the experiments of Marconi, who by using a bent antenna has succeeded in giving direction to the electrical waves. Bellini and Tossi in France have also obtained very satisfactory results by the use of a kind of loop antenna.

In wireless telephony, continuous trains of oscillations produced either by the arc or by means of high-frequency dynamos have been so far improved that the range of working has been increased from about 10 miles to over 200,

A Calorimeter for the Determination of the Specific Heat of Liquids: Mr. H. C. DICKINSON, of the Bureau of Standards.

A Dewar flask of the ordinary spherical form, of five liters' capacity, has been adapted for use directly as a calorimeter for measuring the specific heat of liquids. The particular problem attacked has been the measurement of the specific heat of calcium chloride solutions at low temperatures. For this purpose the flask is immersed in a mixture of ice and water and filled with the solution to be tested, cooled to the lowest temperature its concentration will permit.

The method consists in accurate measurements of the temperature of the weighed contents of the flask, alternating with short periods during which energy is supplied electrically to raise the temperature of the liquid. The temperature is raised by steps of about 5° C. and the energy supplied, and the corresponding rises of temperature are measured for each 5° interval. Such a series of observations with a single sample of solution, occupying about one and a half hours, gives a specific heat for intervals of 5°, between -30° C. and +20° C.

The water equivalent and radiation constant for the calorimeter were determined with great care by a separate series of experiments, using pure water. The water equivalent of the calorimeter, stirrer, thermometer, etc., is only about 2 per cent. of the total water equivalent of the solution used.

The total correction for radiation with a temperature difference of 30°, amounts to only about two per cent. of the energy supplied.

The energy, supplied electrically, is measured to about 2 parts in 10,000 by means of a potentiometer in connection with a standard 0.1-ohm shunt and a volt box.

Temperature differences are measured by means of a resistance thermometer having a sensibility of about 0°.0005 C.

The time intervals necessary in computing the total energy are measured by means of a tape chronograph to about 0.02 second.

The following table gives the values found for the specific heat of solutions of chemically pure calcium chloride and water of different densities, where t is the temperature in degrees C.:

Density	Specific Heat	Temperature
1.07...	$0.862 + 0.00057 t$	(-5° to +15°)
1.14...	$0.773 + 0.00064 t$	(-10° to +20°)
1.20...	$0.710 + 0.00064 t$	(-20° to +20°)
1.26...	$0.662 + 0.00064 t$	(-25° to +20°)

THE FUNCTIONS AND ORGANIZATION OF THE AMERICAN SOCIETY OF NATURALISTS¹

THE American Society of Naturalists was founded, under the name of The Society of Naturalists of the Eastern United States, in 1884, by a group of the leading biologists of the day. Some of these have long since passed away. Others yet remain with us and are among the most active and most distinguished representatives of biological science in America to-day.

The motives underlying this movement are not difficult to discover. They are to be found in the great trend toward an intense specialization which at that time began to attract wide-spread attention and called for great concentration of effort and more exacting methods; in the rapid development of a refined and precise technique; in a growing demand for improved science teaching in schools, and in an appreciation of the fact that the arbitrary distinctions hitherto maintained between the two great schools of biological research must shortly disappear in joint efforts toward the solution of the great problems of life. The logical outcome of this point of view necessitated careful consideration of the relations in which the new order of scientific thought and progress must stand toward methods of research and the constitution of societies and academies of science.

But above all, it became a matter of first importance to determine the relations of the new order to the rising generation and through them to the future specialist and scientist. In other words, it became clear that the methods of science teaching must

¹ Presidential address delivered at the Baltimore meeting, December 31, 1908.

be made to so far conform to the trend of scientific thought and to actual progress, as to secure to the public at large correct conceptions, and to the future student of science a proper basis on which to found more advanced studies. It is, therefore, in no way surprising to find that some of the very first discussions of the newly formed society were directed toward a careful consideration of "methods of teaching" and "the employment of specialists by the educational institutions of the country."

It is not our present purpose to analyze fully the important influences which have extended from these discussions broadcast over the land, carrying with them the full weight of the highest authorities of the day, as it would take us altogether too far from the immediate purposes of this address; but it is, nevertheless, worth our while to point out that the spirit of cooperation in scientific endeavor, the high purpose to influence and improve the standard of scientific thought and effort, and the intention to so dignify and enrich scientific achievements that the society might stand as an exponent of the highest and best scientific thought, and as an inspiration to the rising generation, were ideals which constituted the fundamental concept and have been adhered to during the quarter of a century of usefulness which has marked the career of this institution. It was in this spirit that the society set before itself lofty ideals of usefulness, and in the period that has since elapsed I fail to discover that there has been any retrograde step or any serious lapse from the first declaration of policy. The only opportunity for criticism would appear to lie in the possibility that this policy, while fully maintained, has not proved sufficiently elastic to permit of ready adjustment to altered conditions imposed by the lapse of time and the progress of scientific thought; but I am not pre-

pared at this time to admit that such is, in reality, the case.

This society numbers, to-day, 376 members, among whom we proudly reckon the majority of the leading scientific men of the country, while in its organization it represents a powerful, coordinating and centralizing body for various groups of specialists joined for their particular purposes into small societies devoted to restricted lines of research. Few will venture to deny the preeminent position the society occupies, the great influence it has exercised or the eminent character of its work. Nevertheless, we are suddenly faced with a grave problem which threatens nothing short of the very existence of the organization.

Within the last two years we have heard much to the effect that the society is in a moribund condition, that its usefulness is a thing of the past, and the faint-hearted even insist that it is time for it to gracefully die. These statements have been repeated with such insistence and frequency, in spite of the firm belief of many that the society has a very definite and important function to perform, and that never in its history or in the history of science, was there a time when its efforts and influence were more needed than now—that the more progressive, and, I am also bound to say, the more thoughtful among us are led to consider the situation as one which requires to be dealt with firmly but without further delay, to the effect that the usefulness of the society and its functions must be redefined in the light of present-day needs and present-day conditions, and that it shall be rehabilitated. Or, failing this, that it shall be promptly and finally relegated to the things that have served their purpose and no longer meet a want in the economy of scientific thought and development—that its career must be terminated. This is the direct issue with which every member of

this society is faced to-day, and the result must be determined by the vote which you will presently be called upon to cast.

My task is certainly not a congenial one, but as your president to whom the issue has been presented in a most unexpected manner, it is my duty to bring before you as clear an analysis of the situation as it is possible for me to give, and then leave the final decision in your hands.

In the last presidential address delivered to this society, Dr. McMurrich defined the great function of the Society of Naturalists in a very concrete but comprehensive phrase, when he said that "It makes for the solidarity of those sciences which, in the older days, were included in the term natural history," and he then proceeded to show how the necessary development of the biological sciences in particular wrought a change in the work and character of the society, and even threatened to obliterate its *raison d'être*. It is not my purpose to enlarge upon the line of thought which these remarks naturally suggest, but rather to employ them as the starting point for further consideration of those activities which properly devolve upon an organization of this kind, to indicate further directions of usefulness, and, if possible, convey to the minds of my hearers some small measure of that conviction which assures me that there is, more than ever, an open, fertile and as yet unoccupied field which it should be our special duty to cultivate in the interests of pure science.

One of the essential features in the activity of the Society of Naturalists has been the opportunity for the unreserved discussion of abstract scientific problems in which specialists alone are competent to engage, and who alone could derive benefit from such deliberations. Complete removal from the distractions of social life and large public gatherings, are conditions essential to success, and these conditions have been met

in the past by placing the meetings at the time of the mid-winter recess when members could find a few days of relief from their professional work. So long as these conditions were observed, the work of the society was not only successful, but it commanded wide consideration and respect, and there was an atmosphere of enthusiasm and *esprit de corps* which made membership a thing to be sought for and valued.

The American Association has been accustomed from the time of its organization to hold its meetings in summer, usually the latter part of August or early September. In 1902, however, for reasons which we need not stop to analyze or discuss at this time, the association resolved to hold winter meetings, and to make these events synchronize with the meetings of the Naturalists. By many this unfortunate step was viewed with alarm, since they clearly perceived that there could never be room for two such bodies, occupying such distinct fields of endeavor, and with such distinctive methods and objects, in joint sessions, and that sooner or later there would be dissatisfaction and one must yield.

The American Association, by reason of its very constitution, must always remain distinct and apart from the Society of Naturalists. The two organizations occupy distinct spheres of usefulness which should not be compromised by being brought into too close contact, and it is well that this relation should not only be recognized but maintained, since in that way alone may they strengthen and supplement each other's work in the most effective manner. The great purpose of the American Association is to popularize scientific knowledge and effect its widest distribution. In this way it aims to secure for scientific men the widest recognition and the most perfect facilities for their work. It seeks, therefore, first of all, to gather about a relatively small nucleus of scientific men, the largest

possible popular membership collected from the population of the town or city in which its meetings may be held. No one would think of questioning the value of such a proceeding for the particular purposes of the association, but it will be readily admitted by all that such methods are not in harmony with the purely scientific spirit, that they are inconsistent with sober scientific thought, and that the meetings are not expected to be productive of the best results of investigation. Indeed, it is a matter of common repute that the meetings of the association are not the places for specialists to give serious attention to the problems they are endeavoring to solve, but rather that they afford convenient opportunities for cultivating the social side of scientific life. All this is eminently praiseworthy and desirable, but such work must not be confounded with or allowed to intrude upon opportunities for purely scientific deliberations.

Members of the Society of Naturalists are also in most, if not in all cases, likewise members of the American Association. In such joint membership there is nothing which need imply antagonism or duplication of work, but, on the contrary, such a perfectly natural relation should operate to the advancement of each, particularly of the latter association, by bringing to its ranks the very scientific strength it requires in the execution of its chief function—the popularization of scientific knowledge.

Since the institution of joint meetings there has been a growing feeling that it is impossible to do justice to both interests, that in the multiplicity of sections and societies, of meetings and social functions, there is left no opportunity for the sober work of the Naturalists which has, in consequence, resolved itself into a perfunctory discussion of some large problem of immediate interest. The most recent phase of this particular aspect of the question is

found in the fact that other bodies are now entering this field and thereby tending to still further diminish the value of the work originally undertaken by the Naturalists, through useless duplication and dissipation of energy. The members feel that their time is not being occupied in the way they could wish; that they do not gain from their colleagues the interchange of ideas and experience they had hoped for. Under such circumstances dissatisfaction soon follows; fading enthusiasm treads hard upon the heels of fleeting ideals, and we shortly hear of moribund conditions; references to the greatness of the past and dismal forebodings for the future, coupled with the hope that the society may soon disband. These results must be regarded as the logical expression of forces set in motion when it was decided to establish joint sessions, since it has been observed that during the six years this relation has been in operation, there has been a gradual waning of interest in the public debates, which have also exhibited diminishing importance and force as the leading function of an important scientific body.

It is worth while to recall in this connection that the institution of joint sessions did not affect the Naturalists alone, but involved the Geological Society and all those specialists' societies in affiliation with the Naturalists. From these, complaints and protests are already beginning to be made, and I have it on the best of authority that at least one society is now considering what measures it shall adopt to counteract the undesirable situation in which it finds itself.

It is quite possible that a feeling of indifference or of complacency may have developed among a certain section of the society, and that in the annual house-cleaning which is supposed to take place with the installation of a new executive, there has not been sufficient removal of the waste

of previous years, and a proper introduction of that fresh atmosphere which brings with it renewed endeavor, a broader and more hopeful outlook and the inspiration to new activities and new conquests. I say this because we must be quite sure that neither the whole fault nor even a part of it lies with ourselves. But viewing the progress of events in the light of this qualification, as well as of the fact that we do not stand alone in our dilemma, the conviction is forced upon us that our difficult situation is primarily and chiefly due to the anomalous relations which have been established between us and the American Association. It appears to me, therefore, that while the general sentiment has forced conclusions based upon the alternative of a revision of our relations to that body or extinction, the real issue should be stated in terms of continued companionship. To my mind there should be no question of the society abandoning its chosen field of usefulness in which it has won such distinction. The issue is a clear one and should be won or lost on the simple question as to whether we shall continue to meet with the American Association or choose our own time and place.

Never in the history of the biological sciences, using that expression in its most comprehensive sense, have there been such rapid, extended and far-reaching changes, both of thought and method, as during the last twenty years, and without assuming the rôle of a prophet, it is probably safe to assert that the next two decades will witness even more profound changes. A society such as this, therefore, should always hold itself in readiness to adjust itself to altered conditions, and while exercising a due conservatism, it should, nevertheless, be prepared to meet the situation imposed by altered points of view, new methods, fresh hypotheses, newly ascertained facts and proved generalizations. In such ways

alone does it become possible to infuse new life into those whose ripe experience may excuse a certain degree of complacency; or to awaken enthusiasm in those who are at the threshold of the richest experience that can fall to the lot of man.

Our last president indicated in his address before the society, that the changes introduced by abandoning the generalized methods of the old school of natural history for the more specialized methods of the new school of science introduced some thirty years ago, shortly led to a cleavage between the biological sciences which extended to a similar separation of geology and paleontology. That botany and zoology should become more independent was regarded as both natural and unavoidable, and, from many points of view, most desirable. Viewing the cleavage of paleontology from geology, from the standpoint of efficiency in scientific development, and the normal relations of cognate subjects, we need express no feelings of regret, for however valuable the evidence of fossil forms may be to the geologist as a working force, there is no natural relation between the two. It has, however, been a slow and somewhat tedious process to gain recognition of the fact that paleontology is not a science in itself, and that it does not bear any direct or precise relation to geology; but that it is a composite subject whose chief members belong to the domains of zoology and botany. Were the results of this cleavage to be expressed in no more extreme form than what has been indicated, they might be regarded with seeming indifference, but, as in all reforms, the swinging pendulum has been allowed to continue too far on its one-sided course, and for years the biological sciences have suffered an unsymmetrical development which at times has given rise to many heart burnings and false conceptions of what the science really stands for. The lingering tendency to per-

petuate a distinct scientific status for each of the older subjects, without reference to their cognate relations, has found expression in the recent attempt to organize an independent society for paleontology, a movement which I conceive to be unscientific in spirit, at variance with the present tendency of the times, and one which should receive the prompt discouragement of this and every other scientific body.

When Huxley and Martin introduced their meritorious scheme of general biology, they can hardly be said to have deliberately contemplated the absorption of the entire science of life by either the zoologist or the botanist, but, unfortunately, such was really the outcome of the forces set in motion by them. The relative conditions of development in zoology and botany in their day were such as to lead to the natural conception that a course in general biology must consist of a major quantity of the former and a minor quantity of the latter. This arose from the recognized fact that the development of zoology had proceeded along advanced lines for many years, while botany was yet struggling with questions of taxonomy, nomenclature and general morphology so-called—concerning itself but little with the more important aspects of the subject. It was not until twenty-five years ago that plant physiology, pathology, paleobotany and ecology began to attract attention, either as important educational subjects or as departments of research likely to be productive of great scientific or economic results. It would have been contrary to all human experience had the zoologists failed to promptly seize and exploit the rich fields which lay before them, and botanists have only themselves to thank for the fact that the zoologists not only appropriated their rich inheritance, but delayed a recognition of their rightful share until within the last decade. Gratifying as the present progress in this direc-

tion may be, it is nevertheless far from satisfactory. In many cases our best educational institutions show a lingering conception that botany plays only a subordinate part in any general biological scheme, and that biology is substantially a knowledge of animal life only. Professors even openly advocate courses, or persist in maintaining courses in general biology in which this feature is given special prominence. Among the general public highly educated people commonly discuss botany and biology as wholly distinct and largely unrelated subjects, a point of view for which we can make some allowance when their leaders in science ignore first principles. Such persistent, and one might almost say willful, blindness to the proper correlation of subjects begets a disastrous confusion of ideas and intellectual sterility. Witness the recent instance of a medical practitioner in good standing, and only a few years out of a leading medical school, expounding to a public audience the principles of preventive medicine as applied to tuberculosis. His advice was good, but when he left the immediate field of his own profession for that of science, his statement that "*Bacteria are little animals about half way between a spore and a seed*" was far from comforting to those who had fondly hoped some fertile soil was to be found in the ranks of the rising generation of medical men, wherein to sow the seeds of correct biological principles.

The recently exploited work of Mendel and the brilliant achievements of de Vries, whose results are now being utilized so extensively by zoologists in elucidation of hitherto obscure problems, the light thrown on general biological problems by the long and brilliant array of investigations in plant cytology, the advances in plant pathology which have led to results of the greatest economic importance and have thrown a brilliant side light upon many

obscure problems in animal pathology, recent progress in our knowledge of the laws of hybridization and inheritance, and a dawning recognition of the place which paleobotany properly occupies—all indicate not only that the subject of botany is rapidly gaining its rightful position, but that zoologists are becoming more and more dependent upon a knowledge of plants for a clear and rational explanation of many phenomena of animal life. I do not desire to leave the impression that zoologists as a whole are given to cultivating the erroneous ideas I have endeavored to indicate, because, as a matter of fact, there are many of our leading animal biologists who cheerfully and freely recognize the great and important position of botany as a channel through which some of the most important laws of life receive their best exposition. But that there is certainly need of reform with respect to the general attitude of both our educational bodies and the general public can not be questioned, and that this society should lend its influence in this direction I conceive to be among its most important functions.

The present tendency in science, received as a legitimate inheritance from the great upheaval of the latter part of the nineteenth century, is toward an undue specialization, and an undue haste to attain to the positions occupied by the older men of the professions. The introduction of the system of unrestricted options so fashionable a few years since, has led to efforts to specialize in the undergraduate course, a tendency which still receives far too much encouragement on the part of those whose experience and position should lead them to advise otherwise. My attention is more particularly directed to this with respect to the biological sciences for which a thorough grounding in chemistry, physics and geology is not only indispensable, but because such fundamental knowledge becomes

more essential with every fresh advance that is made. The more deeply one specializes, the greater the need for that help which comes from other fields of learning. Plant physiology demands an accurate and somewhat extensive knowledge of both physics and chemistry. Pathology, to be profitable, must be studied from the comparative point of view. Paleobotany demands an extensive knowledge of geology. What is true of the science of plant life is more or less true of the sciences which deal with life in any one of its numerous phases. For the broad foundations in general science thus required, our educational institutions must provide opportunities for all-round and thorough training, and the present tendency to an early and undue specialization must yield, as it is already giving way to, a more rational group system. Above all, students must be brought to realize that a patient apprenticeship through which the successive steps are taken with deliberation and on the basis of thorough knowledge, is the only medium through which to secure the highest reward and the greatest satisfaction when the goal is finally attained.

Specialization, however, is not confined to individuals, but extends to societies and not only tends to lead them too far from the central idea of coordination, but involves an undue multiplication of organizations engaged in essentially the same lines of work. Such duplication is as unnecessary as it is deplorable.

Specialization is recognized as a necessity of modern scientific development, but its unrestricted exercise involves lack of coordination, narrowness of view, unsymmetrical development. While we fully agree with Dr. Farlow, as expressed in his presidential address before the American Association, that the object of scientific organization is to encourage diversity of work, he would undoubtedly agree with our point

of view that in exact proportion to such diversification or specialization, does it become of increasing importance that there should be a strong, centralizing power operating for breadth of view, coordination of results and a symmetrical development.

Under its present organization the Society of Naturalists is the coordinating and centralizing force for eight other societies which represent the work of specialists in their several fields of activity. These are: The American Anthropological Society, The Physiological Society, The Psychological Society, The American Society of Vertebrate Paleontologists, The American Society of Zoologists, The American Society of Anatomists, The Botanical Society of America, The Society of American Bacteriologists.

It would be a very fitting and natural association if to this important group there were added the Geological Society of America, whose deliberations involve so much in common with some of the other societies, and we may indulge the hope that such a union may be realized in the near future and be so extended as to embrace all of the other specialists' societies not represented at this time. With one or two exceptions this group may very well be regarded as an ideal division of activities without undue subdivision or duplication of work. The only ground for real criticism might be found in the separation of the vertebrate paleontologists from the zoologists, and of the bacteriologists from the botanists. With respect to the former I may reserve my remarks for another connection. With respect to the latter, it might seem better on general grounds that the bacteriologists should be merged with the botanists; but when it is recalled that membership includes many who are not botanists in the general acceptance of that term, that a large number are physicians and zoologists, and that bacteriology involves a peculiar

and elaborate technique, almost exclusively applicable to these minute plants in their various economic relations, it must be conceded that here, at least, there are special reasons for a subdivision which, on other grounds, would not be justified.

It is obvious that specialization among societies may readily be carried too far—much beyond the bounds of scientific requirements. Among botanists this view has made great headway during the last ten years. Thus it is now generally agreed that a satisfactory knowledge and treatment of the science demands familiarity with the extinct forms of plant life, quite as much as with existing types. The methods involved in the study of fossil plants are essentially the same as those applied to the anatomy of recent plants. It is true that a certain and often detailed knowledge of geology is essential in this connection, but this does the botanist no harm and is more likely to be beneficial. The more we are called upon to deal with questions of phylogeny and evolution, the more essential does it become that fossil botany should be as familiar as recent botany. The two are, in fact, inseparable. It becomes clear, therefore, that it is an utterly false conception which endeavors to perpetuate the idea of a separate science of paleobotany. To encourage such a division is to retard the development of the science as a whole, and I am of the opinion that the remarks which apply to botany in this respect must also apply with equal force to paleozoology. No better service to the cause of consolidation, unification of interests and cooperation has been rendered in recent years, than by the union of the Society of Plant Morphology and Physiology and the Mycological Society of America, with the Botanical Society of America. These societies enjoyed separate existence for several years by reason of special circumstances which no longer exist. That the Botanical So-

society of America alone represents all the most important botanical interests of the country is a matter for congratulation.

Under the present system of joint meetings, or, as stated in the most recent official announcement, "under the scheme of affiliation" now in force, the following relations exist between the American Association and the Society of Naturalists, together with the various specialists' societies. Placing the latter in parallel columns with the former, it will be seen at a glance to what an extent there is duplication of work and a conflict of interests between the purely popular side and the purely scientific side.

AMERICAN ASSOCIATION

- A—Mathematics and Astronomy
- B—Physics
- C—Chemistry
- D—Mechanical Science and Engineering.
- E—Geology and Geography
- F—Zoology
- G—Botany
- H—Anthropology and Psychology
- I—Social and Economic Science.
- K—Physiology and Experimental Medicine .
- L—Education.

SOCIETY OF NATURALISTS

- American Mathematical Society.
- American Physical Society.
- American Society of Biological Chemists.
- American Chemical Society.
- Geological Society of America.
- Association of American Geographers.
- Association of American Anatomists.
- American Society of Vertebrate Paleontologists.
- American Society of Zoologists.
- Entomological Society of America.
- Botanical Society of America.
- Society of American Bacteriologists.
- The American Psychological Association.
- Southern Society for Philosophy and Psychology.
- American Anthropological Society.
- American Folk-Lore Society.
- Physiological Society.
- American Philosophical Association.

The large number of specialists' societies here represented makes it clear that their separation from corresponding sections of the American Association for the Advancement of Science must be based upon the impossibility of properly conducting their work in such sections.

It is difficult to conceive what good purpose is served by announcing, let us say, that the American Physical Society will meet jointly with Section B (Physics) of

the American Association. So far as the mere machinery of the meetings is concerned, there is an obvious saving of time and energy; but from the standpoint of scientific results, nothing can be gained for the simple reason that the majority of members of the Physical Society are also members of the American Association, Section B. From this it follows that the Physical Society would be simply meeting *with itself* while preserving the pleasing fiction that it was meeting with some other body.

Our analysis of the relations of the societies shows that there is not only an evident

and unnecessary duplication, but that the work of one body interferes with that of the other; members often know not what meeting to attend; important papers are missed through unexpected changes of program and the impossibility of being in two places at once; confusion reigns supreme. It is clear that some radical and general readjustment of these relations is imperatively demanded in behalf of the general public whose interests are at stake, and for

the welfare of science, which is likely to suffer serious deterioration.

Apart from the considerations thus dealt with, there is another factor of great personal importance, since it bears directly upon the ability of the individual scientist to participate in the work of societies, and makes for the diminution of such organizations rather than their multiplication. In the pressure which is brought to bear upon the scientist to become a member of various societies, it is commonly overlooked that there is an absolute limit to his ability to meet the attendant expenses of such membership together with the ordinary requirements of his position and of his profession, and this limit is soon reached in the case of a large number of men. It was a recognition of this fact that led the Naturalists, some years since, to establish two branches, known as the Eastern and Western Branches, with such a form of organization as would enable them to meet separately or jointly as circumstances might determine. Few scientists are endowed with private means through either inheritance or marriage, and there are certainly several of the professions in which it would be impossible for them to amass even a moderate competency through the exercise of their technical knowledge.

Toronto, Chicago and Columbia have recently been enabled to advance their scale of salaries somewhat in accordance with the advance in the increased cost of living, but the great majority of institutions of learning adhere to the salaries which were barely adequate fifteen or twenty years ago. Taking the most common average salary at \$2,000, an examination of the relations of a college professor to the responsibilities of his profession will probably justify the statement that he is called upon to expend from fifteen to twenty per cent. of his net earnings for the mere maintenance of his position without reference to the require-

ments of progress. "Low living and high thinking" finds neither place nor sympathizers under the present-day conditions, for he who would think high must not only be properly nourished, but his general environment must stimulate, not depress. We are in full accord with the attitude of a recent contributor to *SCIENCE* when he says:

If we take \$2,000 as the average salary of our college professors, we may say that on an average our professors will be drawn from homes where the scale of living is adjusted to the same figure. It should, therefore, be the aim of the college to pay such salaries to its professors as would enable them to give to their children what the college would regard as a perfect preparation for professional work. Only in this way can it draw its teachers from a class in which such preparation is possible.

The conditions indicated impose a grievous burden, and in the face of the education of children and support of families, it is often prohibitive of participation in those activities with which every scientific man should be identified. They carry with them also the additional burden of an undue strain upon the nervous system, and it is now a commonplace that the average professor is in a position of undue stress with respect to ways and means for the necessary expenses imposed by the position he holds, the maintenance of his family and the education of his children. It is within my own observation that this condition has more than once brought men to the verge of despair. It not only denies educated men of the very advantages they are expected to enjoy, but it places a premium upon celibacy and the imperfect education of children. These are not considerations in which sentiment forms a factor, but elements which are directly concerned in the best social organization. But, wholly apart from purely personal elements, putting the case upon the ground of correct business principles and business expediency, we may

safely ask if it is good business policy to engage the services of a highly trained man, impose upon him the most exacting physical and mental labor, and at the same time place him under conditions which compel him to expend from twenty-five to fifty per cent. of his nervous energy in attempts to meet situations altogether foreign to his professional work?

A confirmation of these views comes to us in a wholly unexpected manner through the death, on the twelfth of November last, of one of the most distinguished zoologists of the world. A man of singular modesty but charming personality, he saw in the needs of the younger generation demands which rose superior to all personal considerations. The story comes to us that much needed rest from most exacting labors was refused in the interests of his children. Who will dare say that we have not in this picture an exhibition of the highest type of noble self-sacrifice, and who is in a position to deny that he might yet be with us and prosecuting his work, had he been granted that pecuniary recognition which would have given him an opportunity for the proper care of his children without unnecessary hardship?

If the Society of Naturalists could lend its influence in the direction of an improved public appreciation of the services of the college professor, the real relation he bears to advancement in all departments of intellectual and industrial life, and a proper financial recognition of his services, it would confer upon society at large a benefit for which an adequate standard is difficult to find.

But I must hasten to direct your attention to the problem which demands immediate consideration, "How to find a remedy for the difficult situation in which the society is now placed?"

As the result of a very careful consideration at the hands of your executive body,

and after obtaining a wide expression of views and some detailed plans, a proposition has been formulated which may serve as the basis of action by the society as a whole.

The general sentiment appears adverse to maintaining the society as a mere holding body. This opinion correctly indicates that the society must have some broader and higher function than that implied by an annual banquet and a public discussion. The various affiliated societies must be led to feel that there is a living force which brings them into harmonious relations with all kindred societies; that the central organization deals with the larger and broader questions in a spirit of coordination and in a way not possible to those engaged in the pursuit of specialties; that it lends its active influence in the promotion of research; that it is alive to the interests of the scientific professions, and that it has regard to problems of broad policy—in a word, that it is a living bond which makes for solidarity, community of interests, enthusiasm. The society should not only concern itself with the progress of science, but it is quite as much within its province to have regard for what may be called the economics of the scientific professions—the various conditions which affect the status, welfare and capacity of the individual.

In view of the overshadowing influence which larger and more popular bodies must necessarily exert, it is proposed that, hereafter, the meetings of the Naturalists shall remain independent of other general societies. This does not exclude the use of convocation week, but it does imply that we shall henceforth select some other time and place of meeting than that chosen by any society of a general and more or less popular character.

The present relations of specialists' societies to the Society of Naturalists is satisfactory in principle, though in practice

ways and means may be found to make it more advantageous to all than in the past. It is believed that under the proposed reorganization, it would be highly advantageous to include in the general scheme of affiliation all specialists' societies whose standard of membership is sufficiently high to conform to the requirements of the Society of Naturalists.

To further identify our interests with those of the specialists' societies, it is proposed that all matters of cooperation shall be dealt with by the executive committee, which shall be selected with a view to the establishment of such external relations. This phrase might well be interpreted to mean that each affiliated society shall have its chosen representative on the executive committee of the Naturalists, thereby ensuring the only relation between the several societies through which it will be possible to secure solidarity and identity of interests through cooperation.

It is designed to redefine the general policy in such a manner as to readjust it more definitely to the encouragement of research in the larger fields of science. It should be one of the first objects of our most earnest endeavor to secure a permanent fund which should be devoted to the encouragement of research by any properly qualified investigator within the limits of the United States and Canada, but the subject of investigation should fall within the field occupied by one of the affiliated societies.

The central idea of the society should find expression in some one line of endeavor which makes for the general progress of scientific thought. Of all the societies enumerated, which may be fittingly associated with the Naturalists, there is not one whose work may not be regarded as comprised in general biology, or as having an important collateral bearing upon that science. Whether expressed through the medium of

the botanist, zoologist, physiologist or anatomist; through the more indirect channel of the anthropologist and the folklorist; or through the yet less direct channel of the chemist, the geologist or the physicist, the development of the earth, organic life and even thought itself, is the underlying motive for all. Evolution is, therefore, a great central idea which appeals to all investigators of natural phenomena, and this subject is suggested as one which should be the chief endeavor of the parent body.

In order to give working effect to this idea, it is proposed that each year original contributions dealing with one or more aspects of evolution should be presented to one or more meetings of the Society of Naturalists. Furthermore, it is regarded as desirable that there should be a presentation, annually, of reports upon the most important of recent works dealing with evolution. Both reports and the special contributions should be entrusted to men eminent in their respective fields of research. To occupy a position of this kind should imply a compliment.

It is believed that a general policy, wisely carried out, which keeps alive the enthusiasm for research in the ways indicated, would not only constitute a strong bond of union between the members of the entire organization, making for solidarity of interests, but that it would enlist the sympathy and cooperation of the younger generation of scientists.

D. P. PENHALLOW

McGILL UNIVERSITY

GEORGE WASHINGTON HOUGH

ON New Year's morning, at about ten o'clock, occurred the sudden and unexpected death of Dr. George W. Hough, director of the Dearborn Observatory, at Evanston, Ill. Death came suddenly and painlessly to him, in the way that he had always hoped for it.

after he had come to fulness of years without any break in his intellectual vigor.

He was born at Tribes Hill, N. Y., on October 24, 1836. His ancestors on both sides were German, and old settlers in the Mohawk Valley, the first Hough having come to this country in 1730 from Würtemberg.

Professor Hough was a born astronomer, and grew up filled with the idea of following that profession; it is said that at nine years of age he constructed a contrivance from fish-poles for measuring the right ascension of a star. His mechanical genius, which he inherited from his father, also became manifest about this time, and he harnessed up a small brook to do his mother's churning.

After completing the course in the graded schools and the Seneca Falls Academy, he entered Union College at Schenectady, N. Y., where he graduated in 1856 with high honors.

After graduation he became principal of the first ward school in Dubuque, Iowa, where he remained until 1858, when he entered Harvard University for post-graduate work, taking the degree of A.M. in 1859. The same year he became assistant astronomer at the Cincinnati Observatory.

In 1860 he went to the Dudley Observatory at Albany, N. Y., as assistant astronomer, and two years later was appointed director, which position he held until 1874. It was at the Dudley Observatory that a large amount of his valuable work was done.

His astronomical work consisted largely in the observations of the declination of stars compared with Mars, observations of the planet Neptune, and of asteroids, and observation of Nautical Almanac stars, standard zone stars and small planets.

He invented at this time a machine for cataloguing and charting stars, the principle of which depends on the magnifying by mechanical means the angular motion of the telescope.

In 1867 he began work on the measurement of Struve's list of close double stars, and during the same year made a long series of investigations to determine the amount of the personal equation in transit observations. He made, besides, valuable observations on the

rate of the sidereal clock, and the compensation of the pendulum.

A large part of his time and attention at the Dudley Observatory was given to meteorological work, and in 1865 he invented his recording and printing barometer. The principle of this instrument consists in the transmission of changes in the level of the mercury, by a float resting on the surface of the mercury in the short arm of a syphon barometer. The movements of the float are transmitted by electricity to the moving parts of the mechanism, which repeat this motion and record it. His reports show that more than 50,000 barometer observations were made with this machine in five years. He was awarded a gold medal for this instrument at the Centennial Exhibition in Philadelphia in 1876, and many years later he received a medal for the same instrument at the World's Fair in Chicago in 1893.

Another machine invented at this time was the meteorograph, a machine of simpler construction, which registered hourly the barometer and wet-and-dry-bulb thermometers. Several of the two machines mentioned above were constructed for the United States government.

He also invented an automatic anemometer, which records the velocity of the wind in the form of a curve, prints the results hourly in miles, and also gives the direction, electricity being used as the active agent. He published a long series of observations made with this machine, and was one of the first to point out the intimate connection between atmospheric pressure and the direction of the wind.

Besides these instruments, he invented the first horizontally-driven machine-saw, and also began work on his printing chronograph. He was an expert mechanic, and did all the work on his machines with his own hands.

In 1868 he made a long series of investigations on the Daniel or gravity battery, and was the first to show that lead may be advantageously substituted for copper as the negative plate. He also showed that the substitution of a cell of leather 0.06 inch thick in place of the porous clay cell in the battery produced double the amount of current. Moreover, that the quantity of electricity

flowing in the external circuit depends on the specific gravity of the zinc sulphate, and that polarization in the battery is caused by the saturation of the zinc sulphate.

He made important investigations concerning the velocity of the electric current, and showed that the apparent velocity is directly proportional to the magnetic force of the circuit, but the real velocity can not be measured.

In 1869 he was chief of an expedition of astronomers sent to Mattoon, Ill., to observe the total eclipse of the sun.

In 1870 he was married to Emma C. Shear, daughter of Jacob H. Shear, of Albany, N. Y.

He was elected an honorary member of the German Astronomical Society in 1871. Almost from the beginning of his professional career he took an active part in the meetings of the American Association for the Advancement of Science, and was at one time vice-president.

In the year 1879 he was appointed director of the Dearborn Observatory at Chicago and professor of astronomy in the old Chicago University. His work at once brought Dearborn Observatory into special prominence among the leading observatories of the world.

It was then that he began his systematic study of the planet Jupiter, and this series of observations was continued without interruption for thirty years till the time of his death. These observations included a careful study by micrometer measurements of all the jovian phenomena, especially of the great red spot and the equatorial belts, and made Professor Hough justly famous in the latter days of his life as the greatest authority for that planet. The details and results of these investigations are to be found in the various annual reports of the Chicago Astronomical Society, and in numerous pamphlets published after he came to Evanston.

He also made observations of the satellites of Uranus, and discovered a few new nebulae. During the first few years in Chicago he was associated in his work with Professor Colbert and Professor Burnham.

In 1882 he took up the study of difficult double stars, and is credited with having dis-

covered over 600 pairs, most of them beyond the reach of any but the most powerful telescopes, which gave him the distinction of having discovered more double stars than any other astronomer of his time.

While in Chicago he perfected his printing chronograph, an instrument which is coming into general use in observatories. He also invented an observing seat for the equatorial, which has been adopted by all the leading observatories.

He became interested in the Chicago Academy of Sciences, and served one term as vice-president of that institution.

In 1887 the Dearborn Observatory was moved to Evanston and became part of the Northwestern University. Professor Hough came with it as director, and as professor of astronomy in Northwestern University. During his twenty-one years' residence in Evanston he accomplished a large part of his important work on Jupiter and double stars.

In 1888 he invented a new astronomical dome, superior to anything else of the kind. His inventions here include an absolute sensitometer for testing photographic plates in various kinds of light, an electrical control for the equatorial, an improved form of storage battery combining durability and low cost, a transmission dynamometer for use with the electric motor, and a new and improved form of photographic plate-holder.

In 1891 he received the honorary degree of doctor of laws from Union College, and about the same time was elected a member of the British Astronomical Association. At the World's Congress in Chicago in 1893 he was president of the mathematical and astronomical section. In 1903 he was elected an associate member of the Royal Astronomical Society of England. He was also a member of the Astronomical Society of the Pacific, the Astronomical and Astrophysical Society, the American Philosophical Society, the American Institute of Civics, the Chicago Photographic Society and the Trinity Historical Society of Texas, and at one time a member of the Albany Institute, the Chicago Lantern Slide Club and the Chicago Electrical Society.

In character Professor Hough was quiet

and unassuming, but of an affectionate, genial disposition, and was greatly beloved by all who knew him. His learning and knowledge were vast, and very wide in their scope. He never spoke hastily nor too much, and his opinion on a subject was always worth having. In my long association with him I have often felt the truth of Emerson's words: "Converse with a mind that is grandly simple, and literature looks like word catching."

The sudden death of this great and good man came as an irreparable loss not only to the community but to the whole scientific world.

GEORGE J. HOUGH

DINNER TO PROFESSOR RAMSAY WRIGHT

THE old pupils and colleagues of Professor Ramsay Wright, of the University of Toronto, joined in celebrating the completion of his thirty-fifth year of service in the university by tendering him a complimentary banquet and address on April 15. The chair was taken by Professor J. Playfair McMurrich, the toast to the university was proposed by Professor F. R. Lillie, of the University of Chicago, that to the guest of the evening by Dr. T. MacCrae, of the Johns Hopkins University, and the address was presented by Professor A. B. Macallum. A number of letters from distinguished colleagues of other universities were read, all of which bore ample testimony to the value of the services rendered by Professor Wright in the development of the biological sciences in Canada, in the elevation of the standards of medical education and in the constant maintenance, both by example and precept, of the highest ideals of scholarly attainments. A pleasing incident of the banquet was the reading of a Latin ode composed for the occasion by Professor Maurice Hutton, and of a sonnet by Professor W. H. Ellis, which follows:

From Scotland's mists across the sea you bore
The sacred fire (kindled by him whose name
Has made the century famous with his fame),
And bid our lamp burn brighter than before.
Upon our tree, a branch from Scotland's shore
You grafted, and behold, our tree became
Wanton in leafage; with blossoms all aflame;
Deep rooted; and with boughs to heaven that soar.

We see the better issue from the strife,
And hope the best. In loathsome crawling things
We feel the fluttering of jeweled wings.
In nature's score, with seeming discords rife,
We seek to read, with you, the note that brings
To harmony the jarring chords of life.

THE SHAW SCHOOL OF BOTANY

THE recently issued administrative report of the Missouri Botanical Garden, and an announcement of Washington University concerning the Henry Shaw School of Botany, indicate that the Shaw foundation is on the eve of entering upon a much increased activity. Although Henry Shaw in 1885 endowed a school of botany in Washington University, to the head of which Professor Trelease was called from the University of Wisconsin, the provision made was practically for only a chair of botany. Four years later, on the death of Mr. Shaw, his fortune, appraised at several million dollars, passed to the care of trustees, for the maintenance of his long established and well known garden and the further development of an institution of research and instruction in botany and allied sciences; the head of the School of Botany being selected as its director.

In the twenty years that have since passed, the trustees of the Shaw estate have been compelled to administer their trust on a maintenance basis, seeing approximately a quarter of their gross income absorbed in general taxes and nearly as much more claimed for street improvements, sewers and similar purposes, a large part of which were entailed by the possession of extensive tracts of unimproved real estate within the city limits. Meantime, the revenue of the School of Botany has sufficed for scarcely more than meeting the undergraduate needs of the university. Nevertheless, maintenance of the garden has been made to include the provision of a good equipment in living plants (11,464 forms), herbarium (618,872 specimens) and library (58,538 books and pamphlets). A part of the time of otherwise indispensable employees has been given to botanical investigation, the results of which are published in a series of annual reports begun in 1890,

and fifteen graduate degrees have been earned in the School of Botany.

Though a continuation of high special taxes is anticipated for the next few years, the trustees of the garden hope to see the end of this burden before a great while, and in co-operation with the university authorities they are now prepared to make larger research use of the equipment on hand and begin to provide for graduate instruction to a greater extent than has been possible heretofore. Last year a well designed fireproof building of about 12,000 square feet of floor space was put up. A part of this is being furnished in steel for stack purposes, and the remaining—and larger—part is being equipped for laboratory use. It is now announced that a definite step toward the fuller development contemplated by the founder and planned by the director has been taken in the establishment of the post of plant physiologist at the garden, and the creation of a professorship of plant physiology and applied botany in the Shaw School of Botany, with provision for two research fellowships in botany: in addition to the Englemann professorship held by Dr. Trelease, the assistant professorship held by Dr. Coulter, a teaching fellowship to which Mr. C. D. Learn has recently been appointed, and the honorary post of plant pathologist at the garden held by Dr. von Schrenk.

With this equipment and staff, which are to be gradually increased and are likely to be much enlarged in the near future, it is intended to develop research and graduate instruction and to establish in the broadest sense a course in applied botany, in addition to giving the undergraduate instruction needed in Washington University.

To the new professorship, Dr. George T. Moore has been called, as possessing to an unusual extent the desired combination of established reputation, breadth of view and expert appreciation of the economic applications of botany. The research fellowships are open to capable graduate students from any college, and are believed to offer unusual opportunities for the productive use of talent in investigation. The library, herbarium, and garden furnish the necessary facilities for the

most advanced investigation, and the work in the School of Botany is to be so planned that the individual needs of students engaging in research will be met in every way possible, while leading to the customary degrees.

SCIENTIFIC NOTES AND NEWS

THE following new members of the National Academy of Sciences were elected at the meeting on April 22, 1909: Professor Joseph S. Ames, Johns Hopkins University; Professor Maxime Bôcher, Harvard University; Professor Oskar Bolza, University of Chicago; Mr. Frank W. Clarke, U. S. Geological Survey; Dr. John M. Clarke, New York State Museum; Professor John M. Coulter, University of Chicago; Professor Henry Crew, Northwestern University; Professor Thomas Hunt Morgan, Columbia University; Mr. Waldemar Lindgren, U. S. Geological Survey; Professor Henry L. Wheeler, Yale University. The following were elected foreign associates: Professor Albrecht Penck, University of Berlin; Professor Gustaf Retzius, Stockholm; Professor Wilhelm Waldeyer, University of Berlin; Professor Wilhelm Wundt, University of Leipzig.

DR. ARRIGO TAMMASSIA, professor of forensic medicine in the University of Padua, has been created by the king of Italy a senator of the kingdom.

PROFESSOR G. LUNGE, of Zurich, has been elected an honorary member of the London Chemical Society.

THE founder's medal of the Royal Geographical Society has been awarded to Dr. Stein for his archeological and geographical explorations in Central Asia. The patron's medal has been awarded to Colonel Talbot for his surveys on the northwest frontier of India and in the Anglo-Egyptian Sudan.

ST. ANDREWS UNIVERSITY has conferred its doctorate of laws on Dr. James Wallace, F.R.S., professor of chemistry in University of Edinburgh.

DR. GEORGE LINCOLN GOODALE, professor of botany at Harvard University since 1878, will retire from active service at the close of the present academic year. Professor Goodale

will celebrate his seventieth birthday on August 8.

DR. F. ZIRKEL, professor of mineralogy at Leipzig, has retired from active service.

DR. WILLIAM W. CADBURY has resigned as pathologist in the Henry Phipps Institute, Philadelphia, and sailed for China, where he will aid in the establishment of a University Medical School in Canton.

MR. D. L. VAN DINE, who has been the entomologist of the Hawaii Agricultural Experiment Station for the past seven years, has accepted a position in the Bureau of Entomology at Washington. His work will be on the insects affecting sugar cane and rice in the southern states.

At the meeting of the Board of Directors of the Rockefeller Institute for Medical Research, held on April 10, the following promotions and appointments were made:

Associate Members—John Auer (Physiology), Hideyo Noguchi (Pathology), Alexis Carrel (Surgery).

Associate—George W. Heimrod (Chemistry).

Assistants—Martha Wollstein (Pathology), Richard V. Lamar (Pathology), A. O. Shaklee (Physiology), Gustave M. Meyer (Chemistry).

Fellows—M. T. Burrows (Pathology), Paul F. Clark (Bacteriology).

PROFESSOR H. G. VAN DE SANDE BAKHUYZEN has retired from the directorship of the Leyden Observatory and is succeeded by Mr. E. F. van de Sande Bakhuyzen.

DR. MAX WOLF has been appointed director of the University at Heidelberg in succession to Dr. Wilhelm Valentiner, who has retired owing to ill health.

DR. ERNST KÜSTER, of Halle, has been appointed keeper in the Botanical Institute and Garden at Kiel.

DR. S. SQUIRE SPRIGGE has accepted the editorship of the *Lancet*.

THE State Department has approved the attendance of the following as American delegates at the International Congress of Applied Chemistry to be held in London next month: Dr. Harvey W. Wiley, chief of the Bureau of Chemistry of the Department of Agriculture; Dr. Allerton S. Cushman, of the same depart-

ment; Dr. Frank Wigglesworth Clarke, of the U. S. Geological Survey; Dr. Charles Baeker-ville, professor of chemistry at the City of New York College; Drs. William H. Nichols, Maximilian Toch, Herbert Plaut and Morris Loeb, of New York; Dr. William L. Dudley, of Vanderbilt University, and Dr. L. H. Baekeland, of Yonkers, N. Y.

DR. RAYMOND L. DITMARS, curator of reptiles in the New York Zoological Park, sailed for Europe on May 8 to visit the Zoological Gardens and arrange for the exchange of animals.

PROFESSOR F. L. STEVENS, of the North Carolina Station and College, will during this vacation visit the leading agricultural experiment stations and agricultural colleges of Europe, particularly those experiment stations engaged in work in plant disease or soil bacteriology.

PROFESSOR WILLIAM OSLER, of Oxford, is paying a visit to the United States and Canada. He expects to return to England on July 1.

DR. STELBERG, accompanied by Dr. de Quervain and Dr. Balber, has been sent by the Danish government on a scientific expedition to Greenland.

DR. SKOTTSBERG, the Swedish explorer, has returned from an expedition to southern Patagonia.

MR. DOUGLAS CARRUTHERS has returned from a natural history exploration in the unknown parts of central Arabia.

It is announced in the English journals that Dr. W. Bruce, of the Scottish Oceanographical Laboratory, has made more detailed plans of another Antarctic expedition to leave in 1911, the cost of which is estimated at £50,000. It is proposed to carry on extensive oceanographical work in the South Atlantic Ocean between and south of Buenos Ayres and Cape Town, as well as in the Weddell and Biscoe Seas; to map the coast-line of Antarctica to the east and west of Coats Land, and to investigate the interior of Antarctica in that longitude. Part of the project includes a journey across the Antarctic continent, starting at some suitable base in the

vicinity of Coats Land and emerging at McMurdo Bay, Victoria Land or King Edward Land. The program includes a circumpolar bathymetrical survey, especially in relation to the study of former continental connections. Mr. C. E. Borchgrevink will also conduct a new expedition to South Polar regions. The expedition, the financial and other details of which have already been settled, has been arranged under the auspices of the International Polar Exploration Commission at Brussels.

A PARTY sent by the government to investigate the circumstances connected with the murder by Ilongote tribesmen of Dr. William Jones, of the Field Museum of Natural History, Chicago, has recovered the valuable collection made during the past two years.

At the 665th meeting of the Philosophical Society of Washington, held on April 26, Professor Max Planck, of Berlin, gave a lecture entitled "Die Mechanik als Grundlage der Physik," complimentary to the American Physical Society.

MR. J. G. JACK will conduct a Field Class at the Arnold Arboretum, Harvard University, on Saturdays during the spring and early summer, to assist those who wish to gain a more intimate knowledge of the native and foreign trees and shrubs which grow in New England.

PROFESSOR BASKERVILLE announces a course of lectures by eight or ten recognized experts in the City of New York upon such subjects as water supply, sewage, gas, storage of combustibles, food adulteration, etc.

THE Sioux City Academy of Sciences held its annual meeting on April 13. Its program was devoted to a Darwin memorial which was as follows:

"The Biography of Charles Darwin," Professor H. C. Powers.

"Charles Darwin and the Theory of Natural Selection," Rev. Manley B. Townsend.

"The Principle of Natural Selection as Applied in Education," Professor E. A. Brown.

"A Philosophy Out of Darwin," Rev. Ralph P. Smith.

PROFESSOR F. W. MOTT, F.R.S., began on April 20 a course of two lectures at the Royal

Institution on "The Brain in Relation to Right-handedness and Speech." On April 24 Mr. R. T. Günther began a course of two lectures on "The Earth Movements of the Italian Coast, and their Effects." The Friday evening discourse on April 23 was delivered by Mr. Alexander Siemens on "Tantalum and its Industrial Applications."

HENRY AUGUST HUNICKE, formerly professor of chemistry in Washington University, and later chemist for the Anheuser-Busch Brewing Association and a practising chemical engineer, died at St. Louis on April 5 at the age of forty-eight years.

ALBERT B. PORTER, for ten years professor of physics at the Armour Institute, Chicago, and later engaged in the manufacture of scientific instruments, died on April 17, at the age of forty-three years.

MR. FREDERICK KATO, who was interested in mineralogy, died of pneumonia in his home on Jersey City Heights on April 20, at the age of forty-three years.

DR. FRITZ ROEMER, director of the Senckenberg Museum of Natural History at Frankfurt, has died at the age of forty-two years.

At the meeting of the American Philosophical Society in Philadelphia on April 22, Mr. Edwin Swift Balch presented the following resolution which was passed unanimously:

WHEREAS, The United States in former years made many brilliant discoveries in the Antarctic, including the continent of Antarctica by Charles Wilkes, and

WHEREAS, The United States have not taken any part in the recent scientific explorations of the South Polar regions;

Resolved, That the American Philosophical Society requests the cooperation of the scientific and geographical societies of the United States, to urge on the United States Navy and the general government, that it do make sufficient appropriations to fit a government vessel to thoroughly explore and survey the coast of Wilkes Land, and other parts of Antarctica.

By recent act of the legislature provision has been made for a biological station to be located on the shores of Devil's Lake, North Dakota. An appropriation has been made for building laboratories and providing annual

maintenance. This laboratory will be fortunately situated for the study of many interesting ecological and physiological problems, inasmuch as Devil's Lake is a large body of brackish water with no outlet and represents the collected water supply of a large interior drainage basin. The direction of this laboratory will be under the charge of the biological department of the State University, of which Professor Melvin A. Brannon is head.

THE fifteenth general meeting of the American Electrochemical Society will be held at Niagara Falls, Canada, on May 6, 7 and 8. The retiring president, Mr. E. G. Acheson, has chosen as the subject of his address "The Electrochemist and the Conservation of Our National Resources." The program includes a symposium on "The Electrometallurgy of Iron and Steel," to include eleven papers.

THE New York Botanical Garden offers the following prizes for essays not exceeding 5,000 words, from the income of the Caroline and Olivia E. Stokes Fund for the Preservation of Native Plants: (1) \$40, (2) \$25, (3) \$15. Essays must be typewritten in duplicate and must reach the garden not later than June 20, 1909.

KING LEOPOLD, of Belgium, has decided to grant a prize of \$5,000 to the author of the best work answering the following question: "Describe the progress of aerial navigation and the best means to encourage it." All essays or works relative to the subject and competing for the prize must be sent to the minister of science and arts in Brussels before March 1, 1911. The competition is open to all nationalities. No new edition of any work already in print will be admitted to this competition unless it comprises thorough changes and considerable additions. In case certain sections of any work or essay on the subject have already been published, such work or essay may still be able to enter in this competition providing the last part is published during the time allotted for the competition. The jury will comprise three Belgians and four foreign members. No member of the jury will be allowed to send any work or essay to the competition. The manuscript, work or

essay winning the prize must be published during the year following the one in which the prize will be awarded. Competitors may use French, English, Flemish, German, Italian, Spanish or Portuguese.

THE Hampstead Scientific Society has under consideration a proposal to establish an astronomical observatory and meteorological station on the reservoir near the summit of Hampstead Heath, London. It is proposed to rent, at a nominal charge, a portion of the top of the reservoir near the Whitestone Pond, to build there an observatory house, and to erect the eight-inch reflecting telescope, equatorially mounted, by Grubb, presented to the society some two years ago by Dr. F. Womack; and to establish on the same area a meteorological station, equipped as a "Normal Climatological Station" under the regulations of the Meteorological Office.

ARRANGEMENTS have been made by Professor Foerster, of the University of Berlin, to republish in German an abstract of the documents of the American Association for International Conciliation. Separate articles by Mr. Elihu Root, Mr. Andrew Carnegie, Professor Ladd, of Yale, and Professor Rowe, of the University of Pennsylvania, have been translated into foreign languages, but this is the first arrangement for a general translation and republication.

THE Appalachian Engineering Association will meet in Roanoke, Va., on Saturday, May 8, when the following papers will be read:

"Lead and Zinc Ores in Wythe and Pulaski Counties," by Mr. M. M. Caldwell, of Roanoke.

"Organization and Engineering Difficulties of the Virginian Railway," by Major William N. Page, of Washington, D. C.

"The Virginiana Copper District," by Dr. Thomas L. Watson, State Geologist of Virginia, and Professor of Economic Geology, University of Virginia.

"Geologic Engineering Code of Ethics," by Captain Baird Halberstadt, of Pottsville, Pa.

"Properties and Uses of Mineral Gypsum," by Dr. Frank A. Wilder, of North Holston, Va., ex-State Geologist of Iowa.

The meeting will be followed on Saturday evening by a banquet for the association

and invited guests, tendered by the Chamber of Commerce of Roanoke.

THE fourth annual meeting of the Oregon State Academy of Sciences was held at the High School, Salem, on February 19 and 20, with the following program:

President's Annual Address, A. R. Sweetser.

Illustrated Lecture on Birds, Wm. L. Finley.

"Some Perplexing Problems in the Most Complex of the Sciences," Gaylard H. Patterson.

"Disturbance of Embryonic Nutrition," Ernest Barton.

"The Mineral World," W. A. Miller.

"Some Hymenoptera," C. E. Bridwell.

"The Sea Side Laboratory at Friday Harbor" (illustrated), C. O. Chambers.

"The Kinetic Theory of Matter," B. C. Eastham.

"Denatured Alcohol," C. E. Bradley.

"Problems in Sex Determination," J. F. Bovard.

THE National Association for the Prevention of Consumption has arranged to hold a tuberculosis exhibition at the Art Gallery, High Street, Whitechapel, London. The exhibition will illustrate the extent, cause, spread, prevention and cure of tuberculosis, and will have a special section devoted to tuberculosis in children. It is expected that the exhibition will be opened by the President of the Local Government Board on June 2, and it is proposed that after it has been shown in London it should be taken to various provincial cities and towns.

UNIVERSITY AND EDUCATIONAL NEWS

A BOARD of education has been established in Iowa to control the State University, the State College of Agriculture and the Mechanic Arts and the State Normal School. The board is to consist of nine members, appointed by the governor, and confirmed by the senate, five to be republicans and four democrats. The members of the board serve for six years, one third retiring every two years. The board is to elect a finance committee, of three members, from without its own membership. These three men are to give their entire time to the business management of the institutions, and are to receive salaries of \$3,500 a year.

THE twelfth conference for education in the south was held in Atlanta, Ga., April 14 to 17.

The conference, while discussing general educational subjects, was devoted especially to the improvement of conditions in the open country. The president, Mr. Robert C. Ogden, of New York, gave an address, and the program included addresses on "The American Spirit in Education," by Dr. S. C. Mitchell, the newly elected president of the University of South Carolina; "The National Program in Education," by Dr. Elmer Ellsworth Brown, U. S. Commissioner of Education; "How the National Government may cooperate with the States in Bettering Conditions in the Open Country," by Mr. Gifford Pinchot, of the Forest Service, Washington.

DR. W. F. DEARBORN, assistant professor of educational psychology in the University of Wisconsin, has resigned to take a similar position in the University of Chicago. Dr. B. H. Bode, assistant professor of philosophy in the University of Wisconsin, has resigned to accept a professorship in the University of Illinois.

DR. EDMUND LANDAU, of Berlin, has been called to a professorship of mathematics at Göttingen.

DR. HERMAN KOBOLD has been called from Kiel, to a professorship of astronomy at Berlin.

M. PAUL LANGEVIN has been appointed professor of physics in the Collège de France, as successor of the late M. Mascart.

DISCUSSION AND CORRESPONDENCE

ON GENERIC NAMES

IN a recent issue of SCIENCE, Dr. Hubert Lyman Clark has done good service in deprecating the too familiar practise of naming species after (commonly insignificant) persons. While not a systematic zoologist *sensu stricto* myself, I have had occasion to consult taxonomic works quite extensively for a number of years past, and I am therefore in a position to appreciate the force of Dr. Clark's criticisms. It is my object here to extend their application a little, so as to cover generic names as well. It appears to me that for these last the objection holds with even greater force, since the genus is, theoretically, at

least,¹ a larger category than the species. It is true that we have high precedent for naming genera after persons, as witness the genus *Linnaea*, named for the great master himself by one of his contemporaries. And we have become so accustomed to *Fuchsia* and *Wistaria* that we scarcely ever give thought to their derivation. But what shall we say of *Montagua*, *Grantia*, *Perkinsia*, *Fitzroya*, *Kellia*, *Mitchillina*, *Smithia*, *Jonesia*, etc.? These were all, no doubt, estimable gentlemen who did their share of the world's work; but are their names commanding enough (to say nothing of euphony!) to deserve perpetuation in scientific literature? And if we should take into consideration the question of euphony, what would become of such genera as *Billingsella*, *Girardinichthys*, *Pilsbryoconcha* and *Tarletonbeania*,² or of *Kohlera* and *Dyaria*?³ Any systematist could add indefinitely to this list.

Loyalty to one's friends is a commendable trait, even in a man of science; and a sense of humor is possibly the only thing that saves most of us from suicide or insanity. But there is a time and place for all things. One assumes a grave responsibility in inflicting upon future generations⁴ such philological abortions as those to which I have been alluding.

FRANCIS B. SUMNER

WOODS HOLE, MASS.,

A MENDELIAN VIEW OF SEX-HEREDITY; A CORRECTION

TO THE EDITOR OF SCIENCE: My attention has been called to the fact that in a recent article on sex-heredity published in SCIENCE, March 5, 1909, I carelessly wrote *lugens* for ¹This qualification is inserted in view of the growing custom of creating a separate genus to contain each species.

²This should have been *Tarleton-H-Beania*. Dr. Bean is plainly entitled to damages.

³This last I have on hearsay, but it is far from incredible.

⁴This is confessedly a bit of rhetorical exaggeration. A taxonomic name does not generally endure over five years, if, indeed, it is fortunate enough to be overlooked for so long a period.

lacticolor, on pages 399 and 400, when referring to the pale variety of *Abraxas grossulariata*.

W. E. CASTLE

March 31, 1909

BIOGRAPHICAL DIRECTORY OF AMERICAN MEN OF SCIENCE

THE undersigned will print as soon as the compilation can be made, a second edition of the *Biographical Directory of American Men of Science*. The work is intended to be a contribution to the organization of science in America, and the editor will greatly appreciate the assistance of scientific men in making its contents accurate and complete. Those whose biographies appear in the first edition are requested to forward such alterations and additions as may be necessary or desirable, and to obtain biographical sketches from those who should be included. All those engaged in scientific work whose biographies are not included in the first edition are requested to send the information needed, using, for this purpose the blank that is given on an advertising page (vii) of the current issue of SCIENCE.

It is intended that each entry shall contain information as follows:

1. The full name with title and mail address, the part of the name ordinarily omitted in correspondence being in parentheses.
2. The department of investigation given in italics.
3. The place and date of birth.
4. Education and degrees, including honorary degrees.
5. Positions with dates, the present position being given in italics.
6. Temporary and minor positions; scientific awards and honors.
7. Membership in scientific and learned societies with offices held.
8. Chief subjects of research, those accomplished being separated by a dash from those in progress.

All those in North America should be included in the book who have made contributions to the natural and exact sciences. The standards are expected to be about the same as those of fellowship in the American Association for the Advancement of Science or

membership in the national scientific societies which require research work as a qualification.

The compilation of the new edition will of necessity involve much labor, but this will be materially lightened if men of science will reply promptly to this request.

J. McKEEN CATTELL

SCIENTIFIC BOOKS

The Biota of the San Bernardino Mountains.

By JOSEPH GRINNELL. University of California, Publications in Zoology, Vol. V., No. 1. Pp. 170, plates 24. December 31, 1908.

As a contribution to the zoology and botany of southern California, Mr. Grinnell has given us a paper based on three summers' field work in the San Bernardino Mountains. Its principal sections are: "Life Zones of the Region," with lists of characteristic species of plants of each zone; "Descriptions of Localities," with special reference to their zonal positions; "General Considerations relating to Bird Population; a List of the Important Plants," largely trees and shrubs, with notes on their distribution; "A List of 139 Species of Birds," with detailed notes on distribution, breeding, food and other habits; "A List of 35 Species of Mammals," with notes on distribution, abundance and habits; and "A List of 20 Reptiles," lizards, horned toads and snakes, with notes on range and habits.

It is a great satisfaction to find a fellow worker in the field of geographic distribution who, instead of discovering at once new laws and naming new distribution areas, accepts and follows with conscientious care the general principles of distribution governing the transcontinental life zones and their subdivisions, as worked out by the U. S. Biological Survey. Even the color scheme of the biological survey zone map is followed, with one exception, which is possibly accidental or the fault of the lithographer. This exception consists in using red, which is usually applied to Tropical zone, for Lower Sonoran, which

should have been orange. The colors of the higher zones, yellow for Upper Sonoran, blue for Transition, and green for Boreal, are standards so long in use as to have become familiar to many. Uniformity in such details is helpful to all who use zone maps.

In reviewing a work of such general excellence, and with so few faults, it seems ungracious to attack the first word in the title, but to many of us, either of the long familiar expressions *fauna* and *flora*, or *plants* and *animals*, or for brevity just *life*, would have sounded as well and meant as much as *biota*. However, as this term has been used before, the author escapes the graver criticism of introducing an unnecessary Greek substitute for a good English expression.

The use of the name tamarack, or tamarack pine, for the lodge pole or Murray pine (*Pinus murrayana*), while often used locally where there are no tamaracks, grates on the nerves of those brought up among the real tamaracks (*Larix*), as well as those to whom the name lodge-pole pine recalls camps on the borders of beautiful mountain meadows or the sharp cones of slender tepee poles in the camps of Cheyenne, Arrapahoe, Blackfeet, Crow and Sioux. It may not be possible to correct local misuse of names, but why extend it?

An evident error in the zone map consists in extending Transition zone to the upper limit of *Pinus jeffreyi* instead of confining it to the limits of *Pinus ponderosa*, *Pinus lambertiana*, *Libocedrus decurrens*, *Quercus californica* and the accompanying set of plants and animals. As a result the zone is extended in places at least five hundred feet too high, and the Canadian zone above is correspondingly narrowed. This has apparently resulted from a failure to clearly discriminate between *Pinus ponderosa* and *jeffreyi* and therefore to crediting them with the same range (p. 81). *Pinus jeffreyi* in the San Bernardino, San Jacinto and Sierra Nevada Mountains ranges generally 500 to 1,000 feet higher than *ponderosa*, and by just this much overlaps the lower edge of Canadian

zone.¹ While leading to some confusion in the resulting effort to separate Transition zone into upper and lower divisions, this error is largely compensated by the fact that the vertical range of each species is given and the zones can be checked up thereby. When the zone-marking species are accurately mapped over wider areas, such local defects are easily eliminated.

Approximately ninety pages are devoted to notes on the 139 species of birds, and it is only fair to say that few lists of equal length have contained so much important data on distribution, abundance, migration and habits. A chapter on Bird Population and its Modifying Influences throws much light on local migrations up and down the mountains in pursuit of food, while the bird census and the varying abundance of birds in relation to insect food show the vital importance of birds in an agricultural region. The great number of nesting records, each with date, exact locality, altitude and zonal surroundings, gives for the first time sufficient data for mapping the breeding zones of many of the species in these mountains and furnishes a mine of material for the student of distribution. The nesting habits, food habits, songs, call notes, rare eggs and rare or little known plumages are described and much information that is actually new is put on record.

The notes on 35 species of mammals cover twenty-six pages and are practically all first-hand records of observations on distribution, abundance, food and habits. Many of the species that show local variation or interesting peculiarities are described in detail and in some cases tables of measurements are given. All of these notes are of permanent value and contribute toward a fuller knowledge of our native mammals.

Eleven pages of notes on lizards and snakes

¹The same error of extending transition zone to the upper limit of *Pinus jeffreyi* was made by Dr. H. M. Hall in his otherwise accurate and excellent botanical survey of the San Jacinto Mountains, and in this case also it led to an effort to separate the zone into upper and lower divisions. (See University of California Publications in Botany, Vol. I., pp. 1-140, 1902.)

are of importance in defense of these interesting, useful and much maligned animals.

Besides the colored zone map and transverse section of the mountain zones there are twenty-two full-page plates from photographs of mountain scenery, trees, shrubs, birds' nests and snakes.

The value of such detailed, accurate and reliable local surveys is appreciated nowhere more than in the U. S. Biological Survey, which is working along the same lines over wider fields.

VERNON BAILEY

The Microscope; an Introduction to Microscopic Methods and Histology. By SIMON HENRY GAGE, Professor of Histology and Embryology, Emeritus in Cornell University. Tenth edition. Pp. 359, 258 figures.

The tenth edition of this well-known book on the microscope retains all the meritorious features which have contributed to the success of the former editions. It has been the author's constant desire to have his book represent the "present state of knowledge of the microscope and the technique of its employment." All who have had acquaintance with the former editions (and who among microscopists has not?) know how successful he has been in accomplishing this end. In the present edition, besides incorporating discussions of new or improved features of the microscope and its accessories, additions have been made to the sections dealing with the manipulation of materials.

The same general order of presentation has been followed as in former editions. Of the ten chapters which constitute the work, chapters I.-VII., deal with the microscope and its appliances. Chapter VIII. is given up to various methods of photography (including photographing opaque objects and the surface of metals and alloys, enlargements, etc.) and is rich in practical directions and advice, serviceable to the experienced, as well as to the inexperienced, worker. Chapter IX. is devoted to the preparation of reagents, the making of microscopic mounts, together with notes and comments on materials, methods of storing, and

the like, and is interspersed with numerous useful hints and cautions. In the 48 pages of chapter X., the author gives a concise statement of the fixation, sectioning, staining and mounting of tissues, together with brief discussions of microtomes and section knives, drawings for book illustrations, and the preparation of models. The practicability of the method for making models of blotting paper will appeal to all biological workers.

The book is remarkably free from typographical errors. Only two or three insignificant ones have been noted by the reviewer, as: the omission of the prime marks of $A'B'$, Fig. 15, page 6; *ecently* for *recently*, page 260; and *speeimen* for *specimen*, page 282.

An extended review of the book would be superfluous as its merits are already sufficiently known to the readers of SCIENCE. Its past success is adequate commentary on the author's judgment as to what is needful in a book devoted to the principles involved in making microscopic observations.

MICHAEL F. GUYER

SCIENTIFIC JOURNALS AND ARTICLES

THE April number (volume 10, number 2) of the *Transactions of the American Mathematical Society* contains the following papers:

L. E. Dickson: "General theory of modular invariants."

I. Schur: "Beiträge zur Theorie der Gruppen linearer homogener Substitutionen."

E. J. Wilczynski: "Projective differential geometry of curved surfaces (fourth memoir)."

Edward Kasner: "Natural families of trajectories: conservative fields of force."

G. W. Hartwell: "Plane fields of force whose trajectories are invariant under a projective group."

W. A. Manning: "On the order of primitive groups."

G. D. Birkhoff: "Existence and oscillation theorem for a certain boundary value problem."

Maxime Böcher: "On the regions of convergence of power series which represent two-dimensional harmonic functions."

THE April number (volume 15, number 7) of the *Bulletin of the American Mathematical*

Society contains: Report of the February meeting of the society, by F. N. Cole; "Bézout's Theory of Resultants and its Influence on Geometry" (presidential address), by H. S. White; "On the Representation of Numbers by Modular Forms," by L. E. Dickson; "Note on Lüroth's Type of Plane Quartic Curves," by H. S. White and K. G. Miller; "Cantor's History of Mathematics," by D. E. Smith; "Shorter Notices": Slaughter and Lennes' High School Algebra, by E. B. Lytle; Schoenflies' Einführung in die Hauptgesetze der zeichnerischen Darstellungsmethoden, by Virgil Snyder; Laurent's Géométrie Analytique Générale, by E. B. Cowley; Petit-Bois' Tafeln unbestimmter Integrale, by E. L. Dodd; Annuaire du Bureau des Longitudes, by E. W. Brown; "Notes"; "New Publications."

THE May number of the *Bulletin* contains: Report of the February meeting of the San Francisco Section, by W. A. Manning; "The Construction of a Space Field of Extremals," by E. G. Bill; "The Second Variation of a Definite Integral," by A. L. Underhill; "A Simpler Proof of Lie's Theorem for Ordinary Differential Equations," by L. D. Ames; "Heath's Euclid," by D. E. Smith; "Shorter Notices": Czuber's Differential- und Integralrechnung, by L. W. Dowling; Fabry's Traité de Mathématiques Générales, by C. L. E. Moore; Schubert's Auslese aus meiner Unterrichts- und Vorlesungspraxis and Loria's Passato ed Presente delle Teorie Geometriche, by Edward Kasner; Müller's Führer durch die mathematische Literatur, by G. A. Miller; Voss' Ueber das Wesen der Mathematik, by Florian Cajori; "Notes"; "New Publications."

BOTANICAL NOTES

THE BOTANY OF THE FAERÖES

EIGHT years ago under the general direction of Professor Dr. Eugene Warming the first volume of a comprehensive work on the vegetation of the Faeröes Islands was published simultaneously in Copenhagen (Det Nordiske Forlag) and London (John Wheldon & Co.). It contained 340 pages of text, ten plates and

fifty illustrations in the text. There is first a short historical chapter by Warwing on the earlier botanical investigations of the islands, followed by a chapter of about thirty pages by C. H. Ostenfeld on the geography, geology, climate, etc., in which we learn that there are about twenty islands, of all sizes, from mere islets to the larger islands thirty or more kilometers long and ten to twelve in width. They lie about 7° west of the meridian of Greenwich, and in latitude 62° north of the equator, and are nearly midway between Scotland and Iceland. In general they are mountainous, the elevations reaching to between eight and nine hundred meters. The air is moist and cool, and there is much rainfall (159.3 centimeters—nearly 64 inches).

Following these general chapters are those devoted to Phanerogamae (261 species) and Pteridophyta (24 species), by C. H. Ostenfeld; Bryophyta (338 species), by C. Jensen; Freshwater Algae (323 species), by E. Borgesen; Freshwater Diatoms (248 species), by E. Ostrup; Fungi (168 species), by E. Rostrup, and Lichens (194 species), by J. S. D. Branth.

The second volume, which appeared in 1903, includes papers on marine Algae (216 species), by F. Borgesen; Marine Diatoms (182 species), by E. Ostrup; Phytoplankton from the Sea (93 species), by C. N. Ostenfeld; Phytoplankton from the Lakes (17 species), by F. Borgesen and C. H. Ostenfeld; the Hieracia of the Faeröes (21 species), by H. Dahlstedt, and concludes with a History of the Flora of the Faeröes, by Professor Warming in his peculiarly lucid and interesting style. In summing up his conclusions he says he is fully convinced "that the whole flora—at least all the more highly organized land plants—have immigrated after the glacial period, across the sea, and from the nearest countries, lying east, especially Great Britain."

The third volume, which closes the series, contains more general papers, the first by F. Borgesen being a most interesting ecological study of the marine algae, while those that follow include "additions and corrections" to previous lists of plants, popular plant names, land vegetation, gardening and tree planting,

agriculture, etc. A ten-page paper by Professor Warming—"Field-notes on the Biology of Some of the Flowers of the Faeröes"—is full of suggestive observations. In an appendix of twenty-eight pages F. Borgesen and H. Jonsson present a paper on the Distributions of the Marine Algae of the Arctic Sea and of the Northernmost Part of the Atlantic for the purpose of comparing the Faeröese Algae with that of other portions of the neighboring seas.

Throughout the work the reproductions of photographs, especially of marine algae, are most excellent and some are really quite remarkable.

THE GRASSES OF CUBA

IN a recent "Contribution" from the United States National Herbarium (Vol. XII., part 6) Professor A. S. Hitchcock publishes a "Catalogue of the Grasses of Cuba" which is "based primarily upon the collections at the Estación Central Agronómica de Cuba." Here are deposited C. F. Baker's collections, and the Sauvalle Herbarium. In addition to these Professor Hitchcock has had for study many Cuban collections in the National Herbarium, the collections by Charles Wright (in the Gray Herbarium), and those in the herbarium of the New York Botanical Garden. As a result of his careful studies he is able to enumerate more than two hundred species (228), while Grisebach included 154 and Sauvalle 170.

In the catalogue, in which the only descriptions are to be found in the analytical keys, ten tribes are represented and these include sixty-six genera. The northern botanist misses the *Aveneae*, *Hordeae* and *Phalarideae*, which appear to have no Cuban representatives. More than three fourths of the species are found in the genera of the series *Panicaceae*, and considerably more than one half (135) are in the tribe *Paniceae*. The largest genus (*Panicum*) contains more than a fifth of all the species. Of *Bambuseae* there are seven species, all of the genus *Arthrostyidium*.

As evidence of the commendable conservatism of the author may be cited the fact that he has found it necessary to found but one

new genus (*Reimarochloa*), nine new species, and to change the names (new combinations) in but nineteen cases.

CHARLES E. BESSEY

THE UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

SECONDARY CHROMOSOME-COUPPLINGS AND THE SEXUAL RELATIONS IN ABRAXAS

IN Professor Castle's interesting communication on sex-heredity, published in the issue of SCIENCE for March 5, a view is advanced that is akin to the "provisional formulation" that I recently offered,¹ but seems to me a decided improvement upon it. In the course of his discussion Professor Castle points out that the "XX and X" formula, which holds true for so many insects, apparently can not be applied to the conditions in *Abraxas*, as indicated by the experimental results of Doncaster and Raynor. These results only seem explicable under the view that the relation with which we have become familiar in other insects is here reversed, the female being heterozygous and the male homozygous in respect to sex (Bateson, Doncaster); and with this conclusion I concur. Definite cytological evidence has now been produced that the same is true of some other animals. The work of Baltzer, done in Boveri's laboratory² shows that in the sea-urchin all the sperm-nuclei are alike, while the egg-nuclei are of two classes, approximately equal in number. All of the gamete-nuclei contain 18 chromosomes. In all of the sperm-nuclei and in one class of egg 17 of these are rod-shaped in the metaphase and anaphases of cleavage, and have a terminal attachment to the spindle, while one is a long chromosome that has a subterminal attachment and therefore is hook-shaped. In the other class of egg one of the rods is replaced by a second somewhat shorter hook-shaped chromosome. The latter, therefore, forms a distinctive differential between the sexes; and cytologically considered the female is heterozygous, the male homozygous. A

¹ SCIENCE, January 8, 1909.

² Reported by Baltzer in *Verh. d. deutsch. Zool. Ges.*, 1908, and more recently by Boveri in *Sitzungsber. d. phys.-med. Ges., Würzburg*, 1909.

cytological parallel to the condition inferred from the experimental data in the case of *Abraxas* is thus demonstrated. Furthermore, if the differential chromosome in the sea-urchin is of the same general nature as the X-element of the insects, a confirmation is given of Castle's assumption that in one class of cases (*e. g.*, Hemiptera) XX means the female condition and X the male, while in another class of cases the presence of X means the female, its absence the male.

From the point of view thus given the importance of a cytological study of *Abraxas* is manifest. Thanks to the courtesy of Mr. Doncaster, I have for some time had this material under investigation; but unfortunately it presents great practical difficulties. So much may, however, be said, that while the spermatogonial divisions present a normal appearance, the spermatocyte divisions, in both the hybrid and the pure forms, show remarkably complicated and puzzling phenomena that are unlike anything hitherto described in other insects. A detailed analysis of the distribution of the chromosomes in maturation will, I fear, prove impracticable, and as far as this particular case is concerned we are for the present reduced to mere speculative guess-work. I think, however, that we should not hesitate to guess if indications for direct observation can thus be found.

Professor Castle's assumption is that the "repulsion" between the *grossulariata* factor ("G") and the female-producing factor ("X"), postulated by Bateson, "is doubtless due to the fact that the *grossulariata* character acts as the synaptic mate to the X-element." This is, perhaps, admissible; but from the standpoint of the chromosome-hypothesis it involves the following difficulty. In the heterozygous female (GLX in Castle's formula) G is assumed to couple in synapsis, not with its own homologue or allelomorph, L (as it must do in the male GL or GG), but with a different element, X. The L factor is thus left with no synaptic mate; and this result, when followed out, is found to involve still further difficulties. Even though L be regarded as merely the absence of G, this probably does not mean the absence of an entire

chromosome, but rather the absence from the G-chromosome of a particular pigment-producing factor. I would therefore regard it as a more plausible guess that a Y-element is present in both sexes, and that both have the same number of chromosomes, the female zygote formula being XY and the male YY, as the facts in the sea-urchin suggest. The female heterozygote thus becomes GLXY, the male GLYY, and the homozygous male GGYY or LLYY. All the facts are then consistently accounted for by the single assumption that G, while acting as the synaptic mate of L, always undergoes also a secondary coupling with Y.

Did such secondary coupling not take place the female GLXY would give rise to the bivalents G/L and Y/X, producing the four classes of gametes GX, GY, LX and LY. If, however, in addition to the primary synaptic coupling of X and Y, G also couples secondarily with Y, the result should be a quadrivalent element, which might have either the tetrad grouping

$$\begin{array}{c} \text{GY} \\ \text{LX} \end{array}$$

or the linear grouping

$$\begin{array}{c} \text{G} \\ \text{Y} \\ \text{X} \\ \text{L} \end{array}$$

giving in either case the two classes of gametes GY and LX. In the males, GLYY or GGYY, the gametes will of course be GY, LY or GY, GY respectively. This gives a series of formulas identical with those of Bateson and Doncaster, as recast by Castle, if Y be everywhere inserted in its proper place, as follows:

Parents	Constitution	Gametes	Offspring
(1) Lact. ♀	LLXY	LX, LY	GLXY = gross. ♀
Gross. ♂	GGYY	GY, GY	GLYY = gross. ♂
(2) Het. ♀	GLXY	GY, LX	GGYY = gross. ♂
Het. ♂	GLYY	GY, LY	GLXY = gross. ♀
(3) Lact. ♀	LLXY	LX, LY	GLXY = gross. ♀
Het. ♂	GLYY	GY, LY	GLYY = gross. ♂
			LLXY = lact. ♀
			LLYY = lact. ♂
(4) Het. ♀	GLXY	GY, LX	GLYY = gross. ♂
Lact. ♂	LLYY	LY, LY	LLXY = lact. ♀

This adds nothing in principle to Castle's suggestions, but seems more in accordance with cytological expectation.

Such a mode of coupling may seem very improbable; but I wish to point out that there are at least some approximate analogies to it in cytological facts known in other animals. Several different types of multiple elements, formed by definite chromosome-couplings, are now known. An example is given by *Metapodius* (which I have recently described in detail). In individuals having "supernumerary" chromosomes these regularly couple with the idiochromosome-bivalent in the second division to form triad, tetrad, pentad and even hexad complexes; and the components are often arranged in linear series. I have recently obtained an individual of *M. femoratus* which differs from all other individuals of the species thus far examined in possessing a single odd or accessory chromosome, while the missing small idiochromosome is replaced by a third "m-chromosome." The latter does not, as might have been expected, play the part of a synaptic mate to the odd chromosome, but shows throughout the spermatogenesis the characteristic behavior of its own kind. In the first division it is always coupled with the two other m-chromosomes to form a triad element, the three components almost always forming a linear series. Again, in *Thyanta* there are three sex-chromosomes (the Y-element and two components of the X-element) which divide separately in the first division but are always coupled in the second to form a linear triad series. In the reduvioids, as Payne has recently shown, the sex-chromosomes form in the second division dyad, triad or tetrad groups; in *Gelastocoris* they form a pentad complex; and in each case the components show a definite arrangement and mode of distribution.

A closer approximation to the secondary coupling suggested in *Abraxas* is given by the observation of Sinéty on *Leptynia* (one of the Phasmidæ), and especially by the discoveries of McClung in *Hesperotettix* and some other Acrididæ, that the X-element (accessory chromosome) is in these cases regularly coupled in the maturation-divisions with one of the

bivalents. I have found a somewhat similar condition in the coreid *Pachylis*, though the coupling is here less constant. The most significant fact, emphasized by McClung, is that in *Hesperotettix* the odd chromosome always couples with a particular bivalent that can be distinguished from the others by its size. Such a phenomenon is evidently to a certain extent of the same type as the secondary coupling surmised above as the possible explanation of the facts in *Abraxas*; and it would be most interesting to attempt crossing experiments with these grasshoppers from the point of view that is thus suggested.

Professor Castle's tempting suggestion that the Y-element in the ordinary forms of insects may be the vehicle for the transmission of secondary male characters that are not represented in the female interests me because I had considered an identical view but withheld it for two reasons. One was that in forms like *Pachylis*, *Archimerus*, etc., where the Y-element is wanting, the male secondary characters are as well developed and characteristic as in forms where the Y-element is present. The other is given by the facts in *Metapodius* (since published in the fifth of my "Studies on Chromosomes"). In this case the evidence is nearly if not quite conclusive that the "supernumerary" chromosomes are duplicates of the Y-element; and they are found indifferently in either sex. The closest scrutiny of the original specimens (now in my cabinet) fails to show any trace of the male secondary characters in those females that possess supernumeraries. Since these characters are very conspicuous in *Metapodius* a decisive negative seems to be given to Castle's suggestion, as far at least as three species of this genus are concerned. The Y-element still remains a puzzle; and until it has been satisfactorily accounted for our cytological view of the problem will remain defective.

EDMUND B. WILSON

THE NATIONAL ACADEMY OF SCIENCES

The National Academy of Sciences held its annual meeting at Washington on April 20, 21 and 22. The members in attendance were:

Henry L. Abbot, Alexander Agassiz, J. A. Allen,

George F. Becker, John S. Billings, Franz Boas, William H. Brewer, George J. Brush, J. McK. Cattell, Charles F. Chandler, Russell H. Chittenden, W. B. Clark, George C. Comstock, E. G. Conklin, James M. Crafts, Whitman Cross, William H. Dall, W. M. Davis, W. L. Elkin, S. F. Emmons, W. G. Farlow, Edwin B. Frost, Theo. Gill, Arnold Hague, William F. Hillebrand, William H. Holmes, Joseph P. Iddings, C. Hart Merriam, S. Weir Mitchell, Edward W. Morley, Edward S. Morse, Edward L. Nichols, H. F. Osborn, Michael I. Pupin, Ira Remsen, W. B. Scott, Charles D. Walcott, Arthur G. Webster, William H. Welch, Charles A. White, Edmund B. Wilson, Robert S. Woodward.

The program of scientific papers was as follows:

"The Nature and Possible Origin of the Milky Way," G. C. Comstock.

"Determinations of Stellar Parallax from Photographs made by Arthur R. Hincks and the writer," H. N. Russell (introduced by G. C. Comstock).

"Strange Ceremonial Costumes of California Indians" (with lantern slides), C. Hart Merriam.

"Archeological Problems of the Titiacacan Plateau" (with lantern slides), W. H. Holmes.

"Discovery of a Complete Skeleton of *Tyrannosaurus* in the Upper Cretaceous" (with lantern slides), H. F. Osborn.

"An Iguanodont Dinosaur (*Traquodon*) with the Epidermis Preserved" (with lantern slides), H. F. Osborn.

"Stratigraphic Relations and Paleontology of the Lower Member of the Fort Union Formation," F. H. Knowlton (introduced by Whitman Cross).

"The Deep-sea Bottom of the Eastern Tropical Pacific, from Observations on the *Albatross* Expedition," Sir John Murray (communicated by A. Agassiz).

"The Medusae of the Eastern Tropical Pacific, from Observations on the *Albatross* Expedition," H. B. Bigelow (communicated by A. Agassiz).

"Mythology of the Mewan Indians of California," C. Hart Merriam.

"The Radiation from Gases heated by Sudden Compression," E. F. Nichols and G. P. Pegram.

"Biographical Memoir of Elliott Coues," J. A. Allen.

"Biographical Memoir of Ogden N. Rood," E. L. Nichols.

"The Electrolytic Separation of the Chlorides of Barium and Radium," Edgar F. Smith.

"The Orders of Teleostomous Fishes (Pisces)," Theo. Gill.

"Biographical Memoir of Chas. A. Schott," Cleveland Abbe.

"The Distribution of the Recent Crinoids," Austin H. Clark (introduced by Theo. Gill).

"On the Distribution of Energy in the Spectrum of the Light from Fluorescent Substances," E. L. Nichols and Ernest Merritt.

"A Geographical Excursion in Northern Italy," W. M. Davis.

THE AMERICAN SOCIETY OF NATURALISTS

The annual meeting of the American Society of Naturalists was held in the auditorium of the Physiological Building, Johns Hopkins Medical School, Baltimore, Md., December 31, 1908. Fifty-five members were present.

On vote of the society the address of the retiring president, Professor D. P. Penhallow, in his absence, was read by the chairman, Professor T. H. Morgan. It is printed herewith.

A discussion of the functions and relations of the society followed, participated in by delegates from some of the affiliated societies and by Professors Minot, Davenport, Baldwin and Cattell. This resulted in an emphatic vote in favor of preserving the integrity of the society and of establishing a more effective cooperation between its sections. Professor C. B. Davenport offered a motion that the constitution be amended so that the executive committee of the Naturalists be composed of the secretaries of Sections F, G and K of the American Association and of the secretaries of the technical biological societies affiliated with the Naturalists, the same to form a program committee for the arrangement of papers, times and places of meeting, etc. This motion was referred to the executive committee with power to act.

Professor T. H. Morgan, on behalf of the executive committee, moved first that the study of evolution be the general policy of the society for the ensuing year; second, that the program consist of original contributions on the subject of evolution and of reports, demonstrations, etc., of important recent work in this field. The society voted to adopt this program for the current year. Members from the affiliated societies are accordingly requested to reserve contributions bearing on this topic for presentation before the Naturalists at the next annual meeting.

The place and time of the next meeting was referred to the executive committee.

Eleven new members were elected; they are: D. S. Johnson, Johns Hopkins University; R. C.

Osburn, Barnard College; G. G. Scott, College of City of New York; A. H. Clark, National Museum; L. L. Woodruff, Yale University; N. E. Kellicott, Woman's College of Baltimore, Md.; R. P. Cowles, Johns Hopkins University; J. F. McClendon, University of Missouri; F. B. Sumner, Woods Hole; A. A. Budington, Oberlin College; R. Retzer, Johns Hopkins Medical School.

At an adjourned meeting in the evening the following officers were elected for this year:

President—Professor T. H. Morgan, of Columbia University.

Vice-president and Chairman of the Eastern Section—Professor W. H. Howell, Johns Hopkins University.

Additional Members of the Council—Dr. D. T. MacDougall and Professor Charles H. Judd.

Treasurer—Dr. Herman von Schrenck.

Secretary—Dr. H. McE. Knowler.

Professor R. A. Harper, University of Wisconsin, is vice-president and chairman of the Central Branch of the society, and Professor J. G. Lee, University of Minnesota, is secretary of the Central Branch.

H. McE. KNOWLER,
Secretary

REPORT OF THE BALTIMORE MEETING OF THE AMERICAN FEDERATION OF TEACHERS OF THE MATHEMATICAL AND THE NATURAL SCIENCES

The council of the federation met in Baltimore, Md., on Monday, December 28, at 3 p.m. Of the thirty-three members of the council, nineteen were present either in person or by proxy. The report of the executive committee, presented by Mr. J. T. Rorer, outlined the work of the year in connection with organization, the appointment of a special committee on the bibliography of science teaching, the issue of the November *Bulletin*, and preparations for the council meeting in Baltimore. It pointed out some of the specific questions which might naturally engage the attention of the officers of the federation during the coming year; emphasizing, however, the dependence of successful work on increased financial resources.

The treasurer reported a balance of \$20.20 from last year, as shown in the printed statement in the *Bulletin*. The printing and mailing of the *Bulletin* had cost \$53.00, leaving \$32.80 chargeable to this year's account. Dues from the federated associations for this year had not yet been collected. An auditing committee, consisting of Messrs. L. S. Hulbert and C. H. Smith, was ap-

pointed, and reported later that the accounts were correct.

Interesting reports in regard to organization and methods of work were presented from the following local societies: The Association of Mathematical Teachers in New England, presented by Mr. W. T. Campbell; The Association of Teachers of Mathematics of the Middle States and Maryland, presented by Mr. Eugene R. Smith; The Physics Club of New York, by Mr. F. B. Spaulding; The Association of Biology Teachers of New York, by Mr. G. W. Hunter; The Association of Physics Teachers of Washington, D. C., by Mr. W. A. Hedrick; The New England Association of Chemistry Teachers, by Mr. H. P. Talbot; The Central Association of Science and Mathematics Teachers, by Mr. C. H. Smith; The Colorado Mathematical Society, by Mr. G. B. Halsted; The Southern California Science Association, by Miss T. A. Brookman. All the reports showed active and constructive work under way.

By unanimous consent the following article was added to the articles of federation as adopted at the Chicago meeting:

13. These articles may be amended at any annual meeting of the council by a two thirds vote of the members present provided notice of the proposed amendment has been sent to all members of the council and to the president and secretary of each federated society at least thirty days prior to the meeting.

The following resolutions were unanimously passed:

Resolved, That it is the sense of the American Federation of Teachers of the Mathematical and the Natural Sciences that larger appropriations should be made by Congress for the support of the United States Bureau of Education so as to enable it greatly to increase the scope and importance of its work and to render immediate and effective aid in the promotion of education in the mathematical and the natural sciences; and

Resolved, That the executive committee of the federation be authorized to take such action as may seem to it desirable to further such action by Congress.

Three committees of the federation were authorized as follows: One on a syllabus of propositions in geometry; one on publication and publicity, to report next year on the present needs and facilities for publishing material of interest to the federation, and to make recommendations as to ways and means of improving these facilities;

one to investigate the present conditions of college entrance, to define the attitude of the federation towards college entrance problems, and to recommend action that may tend to unify and simplify college entrance requirements.

The following were elected officers for the coming year:

President—H. W. Tyler, Massachusetts Institute of Technology.

Secretary-treasurer—C. R. Mann, University of Chicago.

Other Members of the Executive Committee—G. W. Hunter, DeWitt Clinton High School, New York; J. T. Rorer, Central High School, Philadelphia; C. H. Smith, Hyde Park High School, Chicago.

Professor R. E. Dodge presented a report of progress from the committee on bibliography, showing that the sections on mathematics, physics, biology and geography were nearly completed.

A letter from Professor D. E. Smith, representing the International Commission on the Teaching of Mathematics, was presented, expressing the hope that the federation would cooperate in its undertaking in due time.

On Tuesday morning, December 30, the federation held a joint session with Section L, Education, of the American Association for the Advancement of Science. The topic, "The Problems of Science Teaching," was discussed by President Ira Remsen and Messrs. G. F. Stradling (Philadelphia), Wm. T. Campbell (Boston), John M. Coulter (Chicago), N. M. Fennemann (Cincinnati) and Lyman C. Newell (Boston), as follows:

President Remsen said:

"A battle that has long been waging has been won—the battle for the recognition of science in the courses of study in schools and colleges. I remember well my first experience as a teacher of chemistry. I had accepted a position in one of the small New England colleges without having examined the equipment. When I arrived in the fall ready to begin work, I found that the institution did not possess a laboratory. I at once applied to the president for one, and he replied: 'What for? I have taught chemistry, and I thought successfully, without a laboratory; and if I could do it, I think you can. This is not a technical school; what the students want is the broad general principles of chemistry.' So I tried to teach without a laboratory. I was wholly unsuccessful; the students learned nothing—in

fact, some of them told me so in later years. The experience was, however, very useful to me, for I learned a great deal from it.

"Now science is recognized; we have laboratories everywhere and laboratory training is regarded as indispensable. It is therefore fitting to ask: What are we doing with our facilities? What results are we obtaining? When the battle was on, men lost their heads—men must lose their heads in order to fight. We thought that if only we could get laboratories, the problems of education would be solved. Is this true?

"Pedagogical problems are hard to solve—it is very difficult to get sound conclusions. How can we tell whether the scientific training is more effective than that of the older type? This is a problem that can not be solved by sitting down and thinking about it; it can be solved only by research and experiment. I do not myself know whether scientific training as now conducted is producing the results hoped for. Yet I am convinced that scientific training, when properly conducted, may be of the greatest value as an educational force. This is quite a different thing from saying that that particular thing now known as science training is of great value. It all depends upon how it is done.

"Personally, I have been guilty of all the sins possible for a teacher of science. I have been experimenting to find out how to teach chemistry; and it is the most difficult experiment I have ever tried. My own experience in school was very instructive to me, for my own education was most unsatisfactory—in fact, I never was educated. My first experience with chemistry was gained in a course of lectures one hour a week by one of the greatest chemists of this country, Professor Wolcott Gibbs. Yet from this course I learned nothing. My second experience came when I had taken up the study of medicine. The teacher knew little chemistry, and I was asked to assist him in preparing the experiments for his lectures. He had a large practise, and left me alone to prepare experiments that I had never seen. I am almost ashamed to confess what happened that year—there were explosions and fires and bungling beyond words. I had little or no guidance.

"In my first course the instruction had been 'theoretical'; in the second I had the 'practical' galore; I therefore thought I was an experienced chemist and could go on and take an advanced course. It was a sad awakening when

I found that I knew practically nothing of the subject.

"But to return to our theme: Are we doing the best that is possible with what we now have? Do the results obtained justify the equipment and time devoted to scientific study? I am not qualified to answer these questions for the schools; but speaking for the colleges, I may say that, in my opinion, the results are frequently quite unsatisfactory. The reason is that we have not yet learned how to deal with the subject. It is not hard to teach chemists chemistry, but it is very hard to teach beginners something that is worth while about chemistry in one year. What can be expected of a one-year course? Have you ever seen students who obtained an intelligent knowledge of any subject in one year? We can not expect anything of great value in that limited time. If getting knowledge of a subject is the purpose, we can not expect much of even the best teachers. But the important point is: Are we doing the best we can under the circumstances?

"There are two points in which, it seems to me, we might do better—two defects that might be remedied. One defect is that the student is not subject to enough supervision in his laboratory work. He is very much in the condition in which I found myself when turned loose in the laboratory to prepare experiments I had never seen. He is turned loose with a book, and then left alone. This is not conducive to scientific work. School authorities do not realize the need of enough teachers for the sciences. The head teacher generally expounds the subject and leaves the laboratory work to inexperienced assistants. It is too much work for the professor to have to spend four or five hours a day in the laboratory with the students. If we could get teachers with interest in their subject and in their students, it would solve the problem; but in science as in other subjects, we are not going to find these often. Unless we can find out how to produce good teachers, we shall fail to get the best results.

"The second important defect in the present teaching of chemistry in college is the absence of repetition. There are too many fleeting impressions. There is a little about a great number of things, as oxygen, hydrogen, chlorine, nitrogen, phosphorus—each being treated as something new with no reminders. In language there is much repetition; each new lesson continually connects with past work. Yet it is only by repetition that we learn. We do not learn a game by being told

how to play and then trying it once. Repetition is largely lacking in science teaching. We cover too much ground. The student gets only a veneer.

Knowledge of this sort is not of much use, and the drill given by such study is not effective. We must introduce into science teaching the drill element that comes only from repetition of the sort that is characteristic of languages and mathematics.

"Chemistry has one kind of work involving repetition of the right sort, namely, qualitative analysis. This field offers good educational possibilities, but the work is in great danger of becoming mechanical. The student is prone to go through the motions with his mind on his book, to guess at the results, to report, watching the reaction of the teacher closely, and to get credit. In order to introduce this element of repetition, quantitative work has been introduced to save the situation. Some quantitative work is desirable. It makes it possible to keep a student at one experiment till he has obtained good results. Such work is monotonous, though it has the advantage of not requiring the student to cover too much ground.

"The remedy for these two important defects is, unfortunately, unattainable at present. We must get good teachers. Much is being done in the way of training teachers, and much that is good is coming from this work. Yet we must not forget that good teachers are not easily made. It is harder to train a teacher to conduct laboratory work efficiently than to train one to teach mathematics or a language. In science the laboratory presents a new problem, and serious errors have occurred and are occurring. Yet, in spite of this, great progress is being made, and there is little doubt that in the end scientific training will fully justify itself in the schools and colleges.

"In closing let me again specifically state that I do not consider myself competent to speak of science training in the secondary schools; all that I have been saying applies, as far as my own definite knowledge goes, only to the colleges."

Dr. G. F. Stradling showed that there has been no notable change within the past decade in the relation of doctorates in physics to the whole number conferred in the United States, nor has any notable change in the proportion of students offering physics upon entrance to college taken place. There has, however, been a very marked decrease in the percentage of all high school students taking physics.

From 1890 to 1906 the high school population became two and three fourths times as great, while the number of students of physics merely doubled. Had the ratio of 1890 held unchanged, 49,000 more students would have been studying physics in the high schools in 1906. In 1890 about 21.3 per cent. of all high school students studied physics, in 1906 only 15.5 per cent. For chemistry the numbers are 9.6 and 6.8. Every year since 1894, without exception, has shown a smaller percentage of students in physics.

From 1890 to 1906 the percentage of Latin students grew from 33.6 to 50 per cent.; of German students, from 11.5 to 21 per cent.; of algebra students, from 43 to 57.6 per cent.

Chemistry, astronomy, physiology, zoology and physical geography all are losing ground in the high school. The sum of the percentages of students in these branches and in physics in the period named fell from 93 to 67 per cent., while the sum for Latin, Greek, French and German rose from 71 to 84 per cent.

Causes suggested for these changes were: (1) introduction of a wider system of electives; (2) lack of well-prepared teachers, and (3) change in the method of teaching.

A commission of the caliber of the committee of ten ought to investigate thoroughly the conditions of science teaching in the United States. An increased appropriation from Congress to the Bureau of Education would help to bring about such an investigation.

Mr. William T. Campbell, of the Boston Latin School, claimed that more attention is needed to the care of students of average mathematical ability. Under the elective system these drift into other paths. Something has been done to make the subject more attractive to them; but more remains to do. It is doubtful whether our present course, even if improved, will meet the situation. Considerable change in the direction of practical work and of closer connection with other sciences is needed.

Professor Coulter pointed out that, while the problems of the teaching of botany were constantly changing, those at present most urgent seem to be: (1) to get the prepared teacher who has a general knowledge of the fundamentals of botany, clear conceptions of the purpose of botany in the secondary schools as distinguished from higher institutions, and ability to attack the subject in a variety of ways; (2) the place of economic

botany or agriculture in the botanical instruction; (3) the biological grouping of subjects; (4) the holding of the interest of the students, i. e., the finding of the effective point of contact for botany with students who are looking for practical values. No formulation of the value of botany can be made until these problems have been settled. The time is now ripe for a well-organized investigation, to be followed by a statement of well-established conclusions.

A full report of the meeting will be issued in pamphlet form early in May. This will be sent to the members of the federation. Any one may obtain copies by applying to the secretary.

C. R. MANN,
Secretary

THE UNIVERSITY OF CHICAGO

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION F (ZOOLOGY)

The vice-presidential address at the Baltimore meeting was delivered by Professor E. B. Wilson. It was published in SCIENCE, January 8, 1909.

The secretary has received abstracts of papers read as follows:

Brood-protection and Sexual Dimorphism among Echinoderms: HUBERT LYMAN CLARK, Harvard University.

The large number of echinoderms now known (about fifty) which protect or care for their young in some way show great diversity in the method used. The eggs may develop outside the body of the parent or more rarely within the body-cavity or in special reproductive cavities. If developed outside the body, the young may become attached to some part of the parent, or be sheltered among her spines or covering plates, or simply be brooded beneath her ventral surface. If developed within the parent, the young may swim about freely in the body-cavity, or more rarely undergo their development in the reproductive organs, which are thus practically uteri.

Among all these brood-protecting species, however, there seem to be only half a dozen (about twelve per cent.) which occur in tropical waters, while more than sixty per cent. are found in Antarctic or South Temperate seas.

Only four species, and these all from between 30° and 60° S. latitude, show any marked sexual dimorphism. In one, an ophiuran, the male has only five arms, the female, six to eight (Koehler). In another, a holothurian, the development of a peculiar brood-chamber in the dorsal integument

distinguishes the female. The third is a spatangoid in which the lateral petals of the female are much broader and deeper than those of the male and serve as brood-pouches. The fourth is a clypeastroid, recently discovered in the Australian collections of the "Thetis," in which the abactinal area of the female is deeply depressed to form a horseshoe-shaped brood-chamber, wholly wanting in the male.

Notes on the Eggs of the Anura of Ithaca, N. Y.:

ALBERT H. WRIGHT, Cornell University.

Eight species of Anura are found at Ithaca, N. Y., namely: *Rana sylvatica*, *Hyla pickeringii*, *Rana pipiens*, *Bufo lentiginosus americanus*, *Rana palustris*, *Hyla versicolor*, *Rana clamitans* and *Rana catesbiana*.

The first five species appear from hibernation and spawn under a maximum air temperature of 43–50° F.; the last three delay until the maximum reaches 70° F. or more. The first five usually breed from the last of March until the middle of June; the last three, from the last of May into August. All but two species, *Bufo l. americanus* and *Rana clamitans*, occupy four or five weeks for the spawning period. The exceptions may require two or three months. The number of eggs may vary from 800 in *Hyla pickeringii* to 20,000 in *Rana catesbiana*.

The eggs of three species, *Hyla versicolor*, *Rana clamitans* and *Rana catesbiana*, float more or less at the surface of the water; the eggs of the other five are submerged. The five species with submerged eggs are the first to breed. They deposit eggs with firm jelly envelopes, several eggs appearing at an emission except in *Hyla pickeringii*, where only one appears at an emission. The three with buoyant eggs breed after May 25. They deposit at the surface masses or films of eggs with loose jelly envelopes, several eggs being deposited at an emission. The best differential egg characters are: the manner of deposition, the nature of the jelly envelopes, the color of the vitellus, the diameters of the vitellus and jelly envelopes, the number of eggs and the season of deposition.

Factors Determining the Movement of Melanin Pigment Granules: OSCAR RIDDLE, University of Chicago.

Movement of these particles from one part of the cell plasma to another, and from one cell to another, is probably determined either by the solubility properties or by the electrical state of the granules. Author obtained no evidences of solubility. The granules are, however, definitely proven to be colloidal bodies bearing a negative

electrical charge—the granules unfailingly moving toward the anode when placed in an electrical field of light intensity. The author thinks this explains not only the movements of independent granules, but the movements of some chromatophores as a whole—as for example the skin chromatophores of lower vertebrates and the retinal pigment of arthropods and vertebrates. And, finally, this fact is of very considerable importance in a consideration of the physiology of color inheritance.

The Rate of Digestion in Cold-blooded Vertebrates in Relation to Temperature: OSCAR RIDDLE, University of Chicago.

By the use of Mett's tubes and a constant temperature tank, information was sought and obtained from cold-blooded vertebrates on the following points: (1) A definite measure of the rapidity of digestion, (2) comparison of this rate in fishes, amphibians and reptilia, (3) seasonal variations in digestive power, (4) a direct and definite measure of the effect of raising or lowering the temperature of the animals, on their rate of digestion, (5) the temperature coefficients of digestion in these animals.

It appears that a gradual loss of digestive capacity has occurred in the amphibia and reptilia during their evolution; and the bearing of this fact on the development of warm-bloodedness in the vertebrata seems to merit attention.

The Hyobranchial Apparatus of Typhlotriton: WM. A. HILTON, Cornell University, Ithaca, N. Y.

The hyobranchial skeleton of *Typhlotriton spelæus* in the adult resembles *Spelerpes* rather than members of the family *Desmognathidae* in which it has been placed. The hyobranchial skeleton of the larva resembles *Spelerpes* much more than the larva of *Desmognathus*. Like *Spelerpes* it has but three branchial arches, while *Desmognathus* has four.

Typhlotriton is a cave form, but from its eyes and other structures it seems to have much more recently come to such an environment than *Typhlomolge*. The hyobranchial apparatus of *Typhlotriton* larva is almost the same as that of the supposed adult, but possible larval form of *Typhlomolge*.

A series of apparently related species beginning with those living in caves only to a slight degree and ending with those best adapted to a subterranean life, is as follows: (1) *Spelerpes longicaudus*, (2) *Spelerpes maculicaudus*, (3) *Typhlotriton spelæus*, (4) *Typhlomolge rathbuni*.

Some Egg-laying Habits of Amphitrite: JOHN W. SCOTT, Kansas City, Mo.

(1) The egg-laying reflex of *A. ornata* is closely associated with the time of spring tide, the height of any given period of egg-laying always occurring within three days of the time of new or full moon. In early summer the period of sexual activity tends to occur after, in late summer before, spring tide. (2) Eggs and sperm float free in the body-cavity, and are usually in various stages of development. Ripe eggs show the metaphase of the first maturation spindle, and eggs in this stage have a greater density than unripe eggs. It is entirely probable that the apparent selection of ripe and rejection of unripe eggs by the nephridia is due to the different effects produced by nephridial currents upon bodies of differing densities.

Bilateral Symmetry in the Development of the Primary Septa of a Living Coral: J. W. MAVOR, Cambridge, Mass.

The usual bilateral symmetry in the development of the first six pairs of mesenteries is shown to occur in *Agaricia fragilis*. The six primary septa are found to be arranged about a plane of bilateral symmetry which is the same as that for the soft parts, and the exosepta are found to arise in bilateral pairs. The bilateral symmetry of the primary septa is found to persist in later stages with well developed epitheca and exosepta. The arrangement of the primary septa in *Agaricia* is different from that in *Siderastraea radians* as described by Duerden, but agrees with that in *Lophophyllum proliferum* as described by the same author.

Autotomy of the Hydranth of Tubularia: MAX MORSE, College of the City of N. Y.

Hydroids commonly absorb their hydranths when placed under artificial conditions. *Tubularia* is an exception, and pinches off the hydranth entirely from the stem. Later it regenerates a new hydranth. There is no disintegration of the cells until after the hydranth has fallen off. Temperature is the active factor in inducing the process; hence *Tubularia* naturally occur fully developed at certain definite periods.

Role of the Nerve System in Regeneration in Earthworm and Newt: A. J. GOLDFARB, Columbia University.

The accumulated evidence points to the conclusion that early embryos and larvae can regenerate missing organs independently of morphogenic influences exerted by or through the nerve system. Concerning the rôle of the nerve system in adults

there is a great diversity of opinion. Experiments upon the earthworm were intended to reexamine the evidence with regard to the influence of the nerve cord on the regeneration of the head. Removal of the cord from the amputated end, for a distance sufficient to prevent innervation of that end, did not inhibit the formation of a functional head.

After determining the number and origin of the nerves supplying the rear limbs and different levels of the tail in the common newt, *Diemyotilus viridescens*, the cells from which these nerves arise were totally destroyed, in both the nerve cord and the ganglia. The cord in the adjoining regions was also destroyed to prevent secondary innervation. Subsequent examination of serial sections established the fact that both the tail and the rear limbs replaced missing parts in the total absence of nerve stimuli, that where under certain special conditions regeneration did not take place, the motor and sensory functional nerves at the amputated end were unable to stimulate the organ to regenerate the lost parts.

Nuclear Components of the Sex-cells of Cockroaches: MAX MORSE, College of the City of New York.

The author presented evidence for: (1) A sex-difference in the chromosomes of the ovary and testis cells, (2) reduction by parasynapsis involving two longitudinal divisions of the chromosomes, (3) the absolute distinction between plasmosome (achromatic nucleolus) and the odd chromosome, contrary to Moore and Robinson, Foot and Strobell, Arnold and others, (4) the individuality of the chromosomes.

Featherless Fowls: R. H. CHAPMAN, U. S. Geological Survey.

The writer called attention to an abnormal condition in chickens seen by him at Delhi, N. Y., during summer and fall of 1908. Some 500 birds of the barred Plymouth Rock breed were incubator hatched between June 5 and 20. Of this number about ten per cent. failed to develop normally—a small number were deformed or became "crazy" after a short time and all (of the ten per cent.) failed in bodily growth and normal feathering. By November 10 all of the naked birds had died. The eggs had come from a farm in the vicinity and the parent birds had been inbred for four or five years.

On the Skull and the Brain of Triceratops: O. P. HAY, Washington, D. C.

This paper questions the correctness of the accepted view that the frill of *Triceratops* has as

its median element the parietal bone. This median element is either a greatly developed nuchal scute or coalesced supratemporal bone. The parietal is that bone which has hitherto been called the supraoccipital. The foramen that Marsh called the pineal foramen, by others the postfrontal foramen, is properly the coalesced supratemporal foramina.

On the Intellect of Animals: ALEXANDER PETRUNKEWITCH, Short Hills, N. J.

Since man can judge of the thinking processes in animals from their actions only, the chief problem is to establish the relation between thought and actions. Conclusions from actions as to presence or absence of reasoning are often based on too little evidence and admit different interpretations. The chief difference in actions of man and those of animals is usually found in the absence of choice in animals. The conclusion which the author supported by new evidence is that reasoning has been gradually developed with the progress of evolution and is certainly to be found in its simpler forms in some higher mammals at least.

Olfactory Nerve, Nervus Terminalis and Preoptic Sympathetic System in Amia calva: CHAS. BROOKOVER, Buchtel College.

The olfactory nerve arises from an ectodermal placode in *Amia*. Nuclei migrate from the placode along the olfactory nerve toward the brain. Some of these nuclei produce sheath cells of the olfactory nerve. Others of the nuclei become enlarged, produce a ganglion two days after hatching, and when the fish is 50 mm. long number about two hundred and fifty cells. Allis homologized this ganglion and its nerve with Pinkus's nerve in *Protopterus*. There are nearly a thousand cells in each adult nasal capsule of *Amia*. They show Nissl bodies. Some are multipolar nerve cells. It is suggested from their relation to the blood vessels that these ganglion cells are vaso-motor in function. About fifty coarse fibers differing from olfactory fibers are found entering the olfactory bulbs. Other fibers extend posteriorly ventrally of the brain. A nervus terminalis is present in *Lepidosteus* and teleosts.

Nerve fibers with ganglion cells inside the cranial cavity were found entering from the profundus branch of the fifth nerve. These fibers innervate the paraphysis and blood vessels of the meninges of the forebrain. Some of the fibers extend forward as far as the nerve of Pinkus (nervus terminalis) and may form a sympathetic

connection with the latter nerve. The pineal stalk is innervated by a bundle of about thirty fibers connecting with the brain just caudad of the habenular body. Intravital methylene blue preparations of the stalk of the epiphysis show ganglion cells with an interlacing plexus of fibers very similar to the sympathetic innervation of the walls of the intestines of vertebrates.

Effects of Brachycephaly and Dolichocephaly upon the Teeth of Man: RAYMOND C. OSBURN, Barnard College, Columbia University.

A study of various types of skulls to show the variations in the dental arch, and especially in the teeth themselves. The principles which have been stated by Professor H. F. Osborn (*Bul. Am. Mus. Nat. Hist.*, Vol. XVI., art. 7) as operating in various groups of lower mammals are here shown in man within the limits of a single species.

Some Noteworthy Additions to the Bryozoan Fauna of our Atlantic Coast: R. C. OSBURN, Columbia University.

A series of lantern slides showing various families, genera and species of Bryozoa new to our east coast fauna. A preliminary report of certain of the more striking forms collected by the author at the Tortugas, Beaufort and Woods Hole stations.

Fission and Regeneration in Sagartia luciae: D. W. DAVIS, Sweet Briar College, Va.

The sexually derived, undivided individual in *S. luciae* is probably a regular hexamerous form with six pairs of complete mesenteries. Of these, two pairs situated at opposite ends of the major transverse axis are directives and each directive pair is associated with a siphonoglyph. A secondary cycle, of incomplete mesenteries arranged in pairs, alternates with the pairs of the first cycle. A third cycle is usually present, and even a fourth may be represented. Longitudinal division is so common that such undivided animals are rare, and fission followed by regeneration plays an important part in the life-history. Fission occurs, almost without exception, in endocoels and, in about two thirds of the cases examined, in complete endocoels. The fission-plane shows a decided tendency to pass at right angles with the major transverse axis, producing bilaterally symmetrical pieces, but with little regard to an accurate halving of the dividing animal.

In regeneration, from eight to ten complete mesenteries are formed, the precise number depending upon the complete or incomplete character of the mesenteries at the boundaries of the old part. The new mesenteries are formed in a

characteristic succession not harmonising with an *Edwardsia* type of development but corresponding to the order described by the Hertwigs for two (possibly regenerating) specimens of *Adamsia*.

Reactions of the Dogfish to Chemical Stimuli: R. E. SHELDON, University of Chicago.

The smooth dogfish, *Mustelus canis* (Mitch.), was tested over the entire body surface, mouth, spiracle and nostrils with acid, saline, alkaline, sweet and bitter substances. The fish was found to be very sensitive over the entire surface to acids and alkalis in very dilute solution. It is less sensitive to salts and bitter substances and does not react at all to sweet solutions. The general body surface, particularly the fins, are more sensitive to alkalis and salts than is the mouth; both are equally sensitive to acids, while the mouth is the more sensitive to bitter substances. When the spinal cord is destroyed no reactions are obtained from the caudal part of the body, showing that the lateral line nerves have nothing to do with these reactions. When the cord is severed from the brain, the caudal part of the animal is more sensitive than before to chemical stimuli. There is no spinal shock after section of the cord. The nostrils are very sensitive to alkalis, acids, salts and bitter solutions. Section of the olfactory crura and different rami of the trigeminus nerve showed that this sensitiveness is due to the maxillaris nerve rather than the olfactory. Parts of the body were overstimulated for tactile response, after which they could always be stimulated chemically. When any region was overstimulated for any given chemical, as an acid, it rarely responded to tactile stimuli, although it usually responded to other chemical stimuli, as a saline or alkaline solution. When cocaine was applied to the skin, tactile response disappeared before chemical. Among the different chemical senses, bitter disappeared first. This sensitiveness to chemical stimuli is due almost exclusively to the nerves of general sensation, not at all to the olfactory nerve and very little, if any, to the gustatory nerves.

Chondrocranium of an Embryo Pig: CHAS. B. MEAD, New York City.

The study of the chondrocranium of *Sus* is of value not only in assisting us to understand the structure of the adult skull in this form, but also on account of its bearing on the general morphology of the mammalian cranium. Owing to its relatively low position in the ungulate series, we would expect many primitive characters to be retained in its cartilaginous cranium, and indeed

this is the fact, for a number of reptilian characters are present.

The notochord, near the middle of its passage through the skull, dips beneath the basal plate and is connected with the dorsal wall of the pharynx in two places. The cartilages which will later form the ear-bones are of the type common to the mammals at this stage of development. A foramen nervus abducens is present. It is in the same position as the similarly named foramen in the reptiles, but the two are not homologous, that in *Sus* being secondary. The cranial cavities in the reptiles and mammals are not strictly homologous, but the cavity in the mammals is larger morphologically than that of the reptiles and has been increased by the addition of the reptilian cavum epiptericum. Vestiges of the primitive side wall of the cranium are found in *Sus*. Taken as a whole, the chondrocranium of the pig is that of a generalized mammalian type. It shows certain specialized characters such as the narrowed anterior portion of the basal plate, the large size of the ear capsules, and the secondary foramen nervus abducens, but these are less striking than the secondary characters of *Echidna*, *Talpa*, *Lepus* or the Primates.

Placentation of an Armadillo: H. H. LAKE, State University of Oklahoma.

The placentation of the Edentates has not been thoroughly studied and only a few observations have been recorded. A female nine-banded armadillo (*Tatu novemcinctum*) in captivity gave birth to four young, and an examination of the deciduate placenta revealed some novel features. There was a complete fusion of the four chorionic vesicles into one. The four amnia were united so as to divide the chorionic cavity into four longitudinal chambers, each with a single umbilical cord attached to its wall. In this specimen the placenta is intermediate in form between the zonary and the discoidal. The villi are present in a broad band surrounding the chorionic vesicle, which is barrel-shaped and has thin membranous ends devoid of villi. The villous band is made up of two disc-shaped areas of very long villi, separated by two bands of very short villi. Each of the two areas with long villi has on its amniotic surface the points of attachment of two umbilical cords. There is no indication of a decidua capsularis. This highly developed placenta would indicate that the armadillo is a specialized form, instead of a primitive type; and if this character is of systematic value, the Edentata are to be regarded as a heterogeneous group and not a natural one.

Cestodes in Flesh of Marine Fishes: EDWIN LINTON, Washington and Jefferson College.

The only common food fishes found to harbor cestodes habitually in the flesh are the butterfish (*Rhombus triacanthus*) and the harvest fish (*R. paru*). The cestode is *Otobothrium oremacolle*. The adult stage has been found in the hammerhead shark (*Sphyrna zygaena*) in New England waters, in the sharp-nosed shark (*Scoliodon terasnovæ*) at Beaufort, and in the cub shark (*Carcharhinus platyodon*) at Tortugas.

In the encysted stage it has been found in twelve species of Woods Hole fishes, in thirteen species of Beaufort fishes and in three species of Bermuda fishes. In all these, with the exception of the butterfish and harvest fish, the parasites were confined to the body cavity where they were encysted on the viscera or in the walls of the stomach and intestine. In the summer of 1908, butterfish to the number of 715 were examined and cysts were found in all but 22. Twelve harvest fish were examined and numerous cysts were found in each. The paper discusses the exceptional position of these cysts in the butterfish and the unusually high percentage of affected fish.

Systematic Relations of the Urodela as Interpreted by a Study of the Sound-transmitting Organs: H. D. REED, Ithaca, N. Y.

This study is the result of the curiosity aroused by the apparent conflicting statements regarding the systematic position and relationships of the various groups of Urodela. Believing that the limits and position of some of the larger groups have been based upon structures which are either affected by environment or negative in their character, and, furthermore, believing that the classification of any group is sounder when based upon results gained from a comparative study of several organs or systems, it was decided to place in evidence a comparative study of the sound-transmitting organs already under investigation with another end in view.

Cryptobranchus is the most generalized. The Ambystomidae are intermediate between *Cryptobranchus* and all other groups. The Plethodontidae and Desmognathidae are departures from the *Ambystoma* stem while from these the Sirenidae and *Amphiuma* seem to be degenerated. *Diemictylus* and *Triton* are identical with regard to these ear structures and differ from all others. They are to be considered the most specialized. Between *Diemictylus* and *Triton* on the one hand and the Ambystomidae on the other *Salamandra* stands intermediate, resembling more strongly the Ambystomidae.

Morphology of the Sound-transmitting Apparatus in the Amphibia: B. F. KINGSBURY and H. D. REED, Cornell University.

Study of serial sections and models of representatives of eight families and seventeen genera of tailed amphibia has shown that there are two skeletal structures fitting in the fenestra vestibuli. The first of these, which we designate as the columella, is connected with the cephalic edge of the fenestra when a connection exists between the ear capsule and columella at all. It bears a more or less well developed process primarily connected with the squamosal bone in *Neoturus*, *Proteus* and *Cryptobranchus*. In adult *Ambystoma*, *Amphiuma* and *Siren* there is a secondary connection of this process with the quadrate. The second element, which we designate as the operculum, has no skeletal connections but affords attachment to a muscle, the m. opercularis of Gaupp. When attachment of this element to the ear capsule occurs it is with the caudal margin of the fenestra. The cephalic end of the operculum is included within the lips of the fenestra vestibuli while in its caudal extent it protrudes. This is the type found in *Diemiotylus* and *Triton*. In the larval *Ambystoma*, at transformation, the columella becomes incorporated with the ear capsule while from the latter the operculum is cut out essentially by an extension of the fenestra vestibuli. In the adult of some forms, e. g., *Diemiotylus* and *Triton*, only the operculum is present while in others, e. g., *Ambystoma* and *Salamandra*, both elements are represented. In still other forms such as *Plethodon* and *Gyrinophilus* both columella and operculum seem to be present and very closely associated, although the developmental stages upon which the final explanation of the morphologic relations depends have not yet been examined.

On the Effects of Centrifugal Force on the Development of the Eggs of the Frog and Sea Urochin: J. F. MCCLENDON, University of Missouri.

The unsegmented egg of *Rana pipiens* subjected to a centrifugal force $= 2,771 \times$ gravity for several minutes, is separated into three layers as follows: a centrifugal yolk layer containing the black pigment granules, an intermediate protoplasmic layer (containing the nuclear elements) and a centripetal fatty layer colored with yellow pigment. Egg material was centrifuged in mass and enough of each layer obtained for certain chemical analyses. Morgan found in 1902 that a certain amount of centrifuging prevented the cen-

trifugal layer from developing. When subjected to more centrifuging no part of the egg develops. When the centrifuged egg partially develops, the centripetal and intermediate layers are more or less mixed in the early cleavage, so I have in the following tables added together the analyses of the centripetal and intermediate layers under the name of the former. Table I. gives the per cent. of water (W.) and solids (S.) in the layers. Table II. gives the per cent. of extracts (E.E. = ether extract, A.E. = alcohol extract, W.E. = water extract) and residue (R.) in the solids. Table III. gives the per cent. of phosphorus (P.) in the extracts and residue. Cp. = centripetal and Cf. = centrifugal layer.

TABLE I.

Layer	W.	S.
Frog: Cp.	74	26
Cf.	48	52
Arbacia: Cp.	88	12
Cf.	79	21

TABLE II.

Layer	E.E. + A.E.	W.E.	R.
Frog: Cp.	51	34	15
Cf.	30	10	60
Arbacia: Cp.	49	20	31
Cf.	38	10	52

TABLE III.

Layer	P. in E.E. + A.E.	P. in W.E.	P. in R.
Frog: Cp.	0.018	1.0	0.4
Cf.	0.54	1.2	1.3
Arbacia: Cp.	2.36	17.0	3.2
Cf.	2.74	13.0	1.6

In Tables I.-III. it is observed that there are great differences between the composition of the two layers, and this is correlated with their different capacity for development.

If the egg of *Arbacia* be centrifuged it is separated first into two and later into four layers. By freezing and crushing the eggs and centrifuging in mass I obtained two layers corresponding to the two first obtained in the entire egg. Centrifugal force has little effect on the development of the egg of *Arbacia*. By inspecting the last two lines in Tables I.-III. it will be noticed that there is very little difference between these two layers in composition, and this is correlated with the fact that there is little difference in their capacity for development.

Centrifugal force causes flattening of the mitosis

in the frog's egg in the direction of the force. This effect of the force is due apparently to compression of the alveolar framework of the egg on one side by the fatty layer and on the other by the yolk layer.

Regeneration and Growth in Fishes: G. G. SCOTT, College of City of New York.

The caudal fin of 117 *Fundulus heteroclitus* of sizes varying from 4.57 cm. to 9.73 cm. long was removed. Fins of the younger fishes (shorter) regenerated proportionately more than the older (longer). In fact the curve representing the proportional amount of regeneration in fishes of different ages (lengths) was regularly descending, resembling one of curve of growth established by Minot. One might conclude that regeneration paralleled growth, i. e., that the power of regeneration is greater in the young. On closer examination we find that each fish (regardless of length) regenerated about 0.6 cm. The following explanation is offered: Regeneration of new fin tissue is due to proliferation outwards in a linear direction of new cells arising from the division of cells exposed by the line of amputation. A fish 5 cm. long contains same sized cells as a fish 10 cm. long and the probability is that the power of proliferation is about the same in the cells of fishes of each size—provided that the cells are at the same relative level in each case. When the amputation was made the author endeavored to have line of removal at same relative place in all specimens. Evidence as to the similar powers of regeneration residing in cells of same level independent of size (age) is shown by the fact that actual regeneration outwards in a linear direction is same in fishes of all sizes. This indicates that regeneration is a process independent of general growth processes. It comes into play under abnormal conditions.

The Early Development of Neurofibrillæ and Nerve Conduction: HANSFORD M. MACCUBDY, Alma College, Alma, Mich.

With the purpose to find the earliest stage at which neurofibrillæ may be discovered in the developing nerve cells and the relation between their first appearance and the establishment of conduction paths as evidenced by the earliest normal movements and reactions to external stimuli, observations were made on the larvæ of *Rana* and *Amblystoma*. Neurofibrillæ are present in the earliest optic nerve fibers and in the retinal elements long before they can perform their regular function. That they are also present in early motor tracts of the neural tube, preceding normal

movements seems amply demonstrated, but further confirmation is to be sought. It appears altogether probable that the neurofibrillæ arise practically contemporaneous with the outgrowth of the nerve fiber.

Regeneration in the Brittle-star *Ophiucoma pumila*, with Reference to the Influence of the Nervous System: SERGIUS MORGULIS, Cambridge, Mass.

1. Is the presence of the nerve essential for the regeneration of the arms in the brittle-star *Ophiucoma pumila*? To answer this question the radial nerve was injured by a red-hot needle near the disc, and then the arm was cut off about the middle of its length. As a control experiment another arm in the same specimen was also cut on at the middle, but its radial nerve was left intact. It was found that in the course of thirty days the arms with radial nerve intact had all regenerated normally, while those with the radial nerve injured produced only a very minute stump of new tissue. If, however, the arm broke off at the place where the nerve was injured—as occasionally happened soon after the operation—no tissue was regenerated from such an exposed surface, although arms in which the radial nerve was intact, even in the same animal, did regenerate.

2. What is the relation of the rate of regeneration to the "level" at which the arms are cut off? It was found that arms cut off at the base or at the middle regenerate much faster than those cut off at the tips.

3. What is the relation of the rate of regeneration to the number of arms removed? The removal of different numbers of arms influences the rate of regeneration of the lost arms only to a small extent; the rate of regeneration when four or five arms are removed is somewhat greater than when one, two or three arms are removed; but this correlation between the degree of injury and the rate of regeneration is not of the nature of a close parallelism.

TEACHERS COLLEGE,
COLUMBIA UNIVERSITY

SOCIETIES AND ACADEMIES

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

THE 432d regular meeting of the society was held April 6, 1909, President Hough in the chair. The following program was presented:

New Chapters in the History of the Coconut
Palm: Dr. O. F. COOK.

It has long been thought that the cocoanut palm presents a perfect example of adaptation to a littoral environment, but this idea is delusive. The tough outer rind which is popularly supposed to have been developed as a protection against sea water is really to guard the cocoanut when it falls, and give it favorable conditions for germination. Cocoanuts require a certain amount of salt in the soil, but this condition is satisfied by soils in some interior localities as well as on the seacoast. Considerable sunshine is also needed. This, however, is met better in arid regions than by a coastal habitat and the care with which the milk is protected would argue in the same direction. Far from being a wild plant the cocoanut does not appear to thrive long away from human beings and in spite of the supposed diffusion of the tree by oceanic currents no instance of the kind is known. A consideration of the varieties of cocoanut palms and the method of their occurrence points in the same direction. Against De Candolle's hypothesis of an old world origin for the cocoanut the speaker brought forward documentary evidence that this palm was spread much wider in America than De Candolle had supposed, so widely as to preclude the possibility of a recent introduction into America. On the other hand, certain Polynesian traditions were cited pointing to an eastern origin for the cocoanut trees among the inhabitants of the Pacific islands.

Mr. Safford in discussing the paper contended for an East Indian origin. He called attention to the intimate connection between this tree and the entire social and economic fabric of Polynesian culture. The absence of cocoanuts from Peruvian graves he considered a strong argument against an American origin and the Polynesian traditions cited by Dr. Cook, he thought, were due to the fact that the oceanic currents in the mid Pacific set westward, leaving wreckage, etc., upon the eastern coasts of the islands. While agreeing with the speaker regarding the origin of the cocoanut in an arid country and its adaptation to human needs through human agency Professor McGee believed that we are very far from the end of the problem which it presents. Dr. Folkmar also discussed the paper briefly and Dr. Cook made a short reply to the criticisms and questions.

Cannibalism in Polynesia: ARTHUR P. RICE.

Mr. Rice remarked upon the wide distribution of this custom and the fact that it had survived to modern times more particularly in Polynesia. Within this area, however, great differences are presented. While Fiji is the classic land of

cannibalism, the very next group, the Tonga Islands, lacked it entirely; it was a custom practised in the Marquesas Islands, but held in abhorrence in Hawaii. In Fiji the custom was a part of the state religion and was demanded by the gods. Revenge upon enemies was the most constant reason for exercising it, but each island kept a black list from which victims were taken on occasion. Those who died a natural death and chiefs were never eaten. Cases were also cited from New Caledonia, the New Hebrides, Samoa and New Zealand. The absence of animals from which a sufficient meat diet could be obtained was cited as a probable stimulant to the great extension of cannibalism over the Pacific, and the modern introduction of such animal diet a contributing cause to its extinction. A partial compensation for the evils of this custom is to be found in the knowledge of human anatomy thereby acquired and the surgical skill resulting, for which the Maori, at least, were noted. The paper was discussed briefly by Dr. Swanton.

The meeting concluded with an exhibition of a collection of Chitimacha baskets recently acquired by the National Museum through Mrs. Sidney Bradford, of Avery Island, La., and an explanation of the designs upon these by the secretary of the society.

JOHN R. SWANTON,
Secretary

THE WASHINGTON CHEMICAL SOCIETY

THE 190th regular meeting of the society was held at the Cosmos Club on Thursday evening, April 8, President Walker in the chair. The attendance was 57.

Professor F. W. Clarke gave a talk in memory of Professor Wolcott Gibbs. Professor Murree, Professor Chatard and Dr. Benjamin related some personal reminiscences of the noted chemist.

Announcement was made that a special meeting of the society would be held at the Johns Hopkins University at Baltimore on April 24. The society granted to the American Chemical Society a waiver of jurisdiction over Virginia, except that part of the state within a radius of twenty-five miles from Washington. Dr. F. C. Cook was appointed the delegate to represent the society at the Seventh International Congress of Applied Chemistry at London.

THE UNTILLED FIELD OF CHEMISTRY¹

Two years ago, upon a similar occasion, it was my privilege to address many of you and to point out some of the relationships existing between the chemist and the community. In so doing, there naturally devolved upon me the pleasant duty of recalling to your minds a few of the great and more significant achievements of members of our profession by way of indicating, although briefly and most inadequately, something of the extent to which the chemist has already placed the community in his debt. It is good for any body of men, animated by a common purpose, to take, from time to time, mental stock of what they have accomplished and of the relation in which they really stand to their environment. Where, as in our own case, the record is one of which we all may well be proud, its contemplation brings a new sense of the dignity of the work itself, a pride of fellowship and an incentive to increased endeavor.

We move, however, in a world where it is easy to take much for granted, where symbols and conventions quickly come to take the place of the realities they represent. Our mental processes are apt to run along the line of least resistance and the apparent and the obvious obscure the fundamental truths. This being so, we can well afford to leave our achievements in the security of the past while we consider for the moment the things we have left undone.

The volume of chemical literature has become so great, so many compounds have

¹Address intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

¹Address of chairman of the Division of Industrial Chemists and Chemical Engineers, Baltimore, December 29, 1908.

been described and classified, so many methods have been laid down, so much detail confronts the student, and his field of study has been so subdivided as to suggest and foster the delusion that the total sum of chemical knowledge must be vast indeed. Vast in its detail perhaps it is, but lacking in those fundamental unities which out of the confusion of detail bring wisdom. Chemistry still awaits its Newton. It still justifies the estimate of Kant, who said of it more than one hundred years ago:

Chemistry is a science, but not a science in the highest sense of that word; that is a knowledge of Nature reduced to mathematical mechanics.

Despite the immense amount of dry detail which we have accumulated, and in some measure correlated, chemistry is still in the imaginative era where generalizations are more the result of happy inspiration than of close mathematical analysis.

Chemistry concerns itself with the changes which matter undergoes in its varying relations to certain forms of energy and yet we do not know what matter is nor have we any conception of the real nature of energy. One has only to state in their ultimate terms the problems confronting us to bring a realization of how very far from their solution we still stand. They are, for instance, thus summarized by Karl Pearson: *What is it that moves? Why does it move? How does it move?* Where, yet, I ask you is their answer to be found in chemistry?

We have built our science upon the assumption that matter, whatever that may be, is composed of indivisible atoms, of a comfortable and ultimate simplicity, only to find that the atom is in fact divisible and that its structure is undoubtedly complex beyond imagination. As to those phases of energy which are concerned with chemical change, even so great a philosophical chemist as Ostwald says:

Chemical energy is to us the least known of all the various forms, as we can measure neither it nor any of its factors directly. The only means of obtaining information regarding it is to transform it into another species of energy.

So we have gone on for a hundred and fifty years transforming chemical energy into electrical energy or into heat, making minutely refined measurements of the relatively small amounts of energy appearing in our processes, while wholly unconscious all this time of the stupendous stores of potential energy which we now vaguely begin to realize are bound up in matter.

Our study of matter has led us to teach that it manifests itself in some seventy distinct and separate forms which we call elements, and yet our very definition of an element is a confession of our failure. An element is something which we have not been able to decompose into anything simpler. We have discovered some curious and interesting relationships between the elements which point to their common origin. In his heart each one of us believes that they must have had a common origin and that the cycles of development which they exhibit can only have resulted from the action of a periodic variable upon a constant, and yet we very rarely even consider the question of their genesis or why their properties are what they are. We are content to regard them as so many distinct creations. The discovery of a new element is hailed as marking an epoch in the history of our science when our real business should be the elimination of the elements as such.

In their interactions, the elements, as we know them, manifest valences and selective affinities which determine the course of all chemical change, and yet we are without an acceptable working hypothesis of the cause and nature of either valence or chemical affinity. Our ideas regarding the constitution of the molecules of many

compounds have been developed in great detail and have led us to so many happy conclusions which the facts have verified as to justify our belief that these ideas must rest upon a substantial basis of truth. This sometimes leads us to forget that the graphic formulas which we build up and write on a plane surface are an attempt to represent in terms of two dimensions actualities which exist in three. Moreover, these formulas depict the molecule as something fixed and rigid, although everything tells us that the atoms within the molecule are in rapid and ceaseless motion. A new chemistry will dawn when we take proper cognizance of these motions and their influence upon the properties and relations of the compound. We state molecular weights with a finality of assurance, forgetting that we know very little of the molecular weights of liquids and nothing of the molecular weights of solids. We write cellulose as $(C_6H_{10}O_5)_n$, but the unknown n is probably the most significant part of the entire formula.

Sulphur passes before our eyes from the crystalline to the amorphous variety, phosphorus assumes the red or yellow form, and an almost complete change of properties attends the transformation. Carbon exists in several markedly different states, and yet as to the meaning and mechanism of these molecular changes we remain in complete ignorance. Fortunately for the comfort or even the very fact of our existence upon the planet, water is denser at 4° than it is at zero. Had it not been so, our lakes and oceans would be simply so many solid ice masses upon which the summer sun could make only a superficial impression, but, in spite of the paramount importance of the fact itself no one of us can say why the water molecule presents this curious anomaly. We write the water molecule as H_2O and commonly regard it as a relatively simple compound. How

then shall we account for the fact that the dielectric constant or specific inductive capacity of water is about fifty times that of air, or perhaps ten times that of glass. As the dielectric constant is in a sense a direct measure of the massiveness of the molecule, are we not forced to the conclusion that the water molecule really is built up of many of these H_2O groups? How else, indeed, shall we explain the power of water to knock asunder the molecules of electrolytes which it dissolves, and does not this complexity of the water molecule bear some relation to the essential part which water plays in the ultimate phenomena of living matter?

And this brings me to the main point of my thesis. A great German chemical company tells us in an attractive book just issued that it employs 218 chemists, 142 civil engineers, 918 officials, and nearly 8,000 workmen. It covers an area of 220 hectares, has 386 steam engines, 472 electric motors, and 411 telephone substations. Its plant represents the highest development which industrial chemistry has reached, but, none the less it can not produce an ounce of starch which a potato growing in the ground fabricates from water and carbonic acid gas under the influence of sunshine.

True it is that this great aggregation of engines and dynamos, furnaces, retorts and stills, can, under the direction of its highly trained and specialized chemical staff, produce certain natural products in condition so available and pure as to even improve upon nature, but by what monstrous effort is it accomplished? In the spring the tender grass and the delicate unfolding leaves cover the whole earth with the green of chlorophyll. There is no noise, no smoke, no stench. The grass is cool and grateful to the touch, and clean. In similar manner vegetation everywhere is fabricating cellulose to the extent of sev-

eral billion tons each year, and not only cellulose, but all the countless other complex products of the vegetable cell. What shall we say of our own chemistry in the face of facts like these, except that we have gone far enough to encourage a faint hope that we may some day be able to approach such methods. Professor Wheeler has defined so clearly a thought which has been in my own mind for years that I can not do better than quote his words. He says:

The vegetable cell is a laboratory in which are carried out a most remarkable series of chemical reactions. As we contemplate the immense number of organic compounds of all degrees of complexity which are formed within this wall of the plant cell we are convinced that this is the chemical laboratory *par excellence*. Two features impress us particularly; first, the silence in which the operations are carried on; second, the narrow range of medium temperatures required. Notwithstanding this apparent simplicity of conditions, the products are of the most various kind. Some of these man is able to synthesize in his own crude way; others are still the secrets of nature. It is utterly impossible for man to prepare certain naturally occurring compounds except at a temperature which would burn the plant tissue. We are led to wonder whether forces exist with which we are unacquainted or whether we are merely unable to control the forces already familiar to us. It would be difficult to say which supposition is the more probable. It will be granted that investigation into the activities of the cell is of profound importance. In fact it has been said that "it is in the plant cell where synthetic operations are predominant, that we have to look for the foundation of the 'new chemistry' which may be expressed broadly as the relation of matter to life."

I expressed two years ago my own belief that the distinctions which we now regard as fundamental between living matter and dead matter would soon break down. This break will, in my opinion, come through the study of the colloids which are the link between matter which we regard as living and that which we regard as dead. At this point, I can not refrain from volunteering a suggestion. We know that

the atoms within the molecule are in rotation. It must follow that as the complexity of the molecule increases more and more of its motion of translation must be converted into rotary motion. In the colloidal molecule we know that many simpler molecules are linked together, and in the molecule of living matter, what? May it not be merely that the more or less haphazard and confined movements of the molecules, which together build up the colloid, are in the molecule of living matter coordinated and controlled in a manner which suggests the vortex. Dead matter drawn within this vortex would partake of this movement and exhibit the phenomena of life. Matter thrown off tangentially would resume its rectilinear course and become, for the moment, dead.

When we consider that in theory at least, in which accidents are barred, a tiny bit of living jelly, an amoeba for example, can endow with life an ocean of its proper pabulum, it seems obvious that the forces which are to manifest themselves in the phenomena of life are already existent in the pabulum, and that what the living jelly does is to induce a coordination and direction of the atomic movements which then take on the vital aspect. Do we not have something roughly analogous to this in the magnetization of successive pieces of steel drawn across a lodestone? A certain coordination of movement in the molecules of the steel has been induced and magnetism results. So in some manner far more complex life, I believe, may be epitomized as coordinated motion.

The subject-matter of such speculations lies so far outside our present-day chemistry as to almost require apology for their presentation, but they are well within the subject-matter of the chemistry of the future, for, to again quote the words of Pearson:

The goal of science is clear; it is nothing short of the complete interpretation of the universe.

Or as Muir has put it:

The great business of chemistry is to force men into close contact with some aspects of external realities and, with the help of her sister sciences, to remove everything that prevents the full vision of nature.

ARTHUR D. LITTLE

*THE FUNCTION AND FUTURE OF THE
TECHNICAL COLLEGE¹*

THAT the education of the child through the first eight years of school should be at the public expense is a matter generally accepted as fundamental by every intelligent voter in this country. There are, however, those who insist that public funds should not be used in carrying on schools of secondary rank; and that the expense of college or advanced technical training should be met and universities sustained by the state is a proposition many would combat. The teaching of trades at public expense, a matter that a few years since was considered impossible by trades unions and society generally, is slowly but surely making its way in this country. If we are to witness, in the next decade, such advances in the scientific, commercial and industrial world as would appear commensurate with the progress of the past ten years, it will be largely due to the work of the technical schools, and colleges of science and engineering—institutions under state control as well as those on private foundations.

As the opportunity and field for such institutions are becoming vastly greater and broader and the need for technically trained men more and more apparent, the fact is also clear that the training in such schools is too narrow and restricted. This is but the natural revolt against the old scholasticism. From a college training in

letters merely, the tendency has been strongly marked in the opposite direction, and pure science and technique in the abstract has characterized the technical courses.

In these institutions men must be prepared, not alone to carry out the will of another; not simply to be exact machines to execute the plans presented to them. The product of these schools must possess initiative, imagination, individuality; they must be experts, leaders, investigators, executives; they must plan and lead, not follow merely; they must create as well as construct. In other words, continued progress means that technical education must produce executive engineers and industrial experts. For these men of the future we must rely upon the endowed institutions, of which there are all too few of high grade, as well as upon public institutions ranking with the former and offering all the advantages of study and research.

The time will soon be upon us when, forced to sustain a much greater population than we now have, and owing to keen competition with foreign countries, the industrial and commercial development of this nation will demand experts in many lines. The depleting of our forests not only robs us of timber needful in developing the arts, but in certain sections of the country will so affect the water supply as to produce regions dry and arid; the storing of water in reservoirs for purposes of power, consumption and irrigation is a matter hardly yet begun; the building of railroads, canals, electric lines; the bridging of rivers and the draining of swamps; the constructing of a system of highways and thoroughfares from city to city and throughout rural districts; the development of scientific farming, the greatest industry before our people to-day; the building of harbors; the perfecting of our great mining industries; these are some of the enter-

¹Elaboration of an address before the Technical Education Department of the National Education Association, July, 1907.

prises for which trained men are needed, and the technical school must furnish them.

In using the term "technical college," there is implied a more extended field than that covered by the college of engineering as the latter is generally understood. In its broad aspects the technical college comprehends work in general science, in mechanical, electrical and civil engineering, mining and chemical engineering, hydraulics, architecture, steam, marine and railway engineering, sanitary science, forestry, agriculture, horticulture and the various subdivisions of these comprehensive and inclusive phases of scientific and industrial life.

The very breaking up of any one of these several branches or subjects gives us at once the clew to the necessity for more intensive and more extended work in the departments they represent and shows clearly the necessity for training an increasingly large number of competent men. While many who might pursue technical courses are far removed from the special school, still the duty of extending and carrying on the work must rest in no small degree with these schools, as so few state institutions at present offer adequate courses in these lines.

In the old days before electricity was used as motive power or for purposes of illumination, when building construction was almost entirely with wood, and work in the arts demanded at best small quantities of iron and steel with little stone or brick and no concrete, when work by hand had not been supplanted by the labor-saving mechanical devices, when problems of transportation by land and water, of heating, lighting, water supply, sewerage and drainage, of bridge and road building, of scientific agriculture were as yet undeveloped, the demand for technical education was small. In the mechanical world the civil engineer was the man of the hour.

He who could establish a grade or construct a single span was in the front rank. Mechanical and electrical engineering courses, as such, were in embryo. The work of the mining engineer was done by rule of thumb. The "cut and try" method was applied in chemistry and architecture. Sanitary science was in an elementary stage. The study of hydraulics was theoretical rather than applied. Forestry, agriculture and horticulture were carried on in the belief that "nature must take her own course."

But the application of scientific principles in the arts and industries has made possible an evolution that has resulted in a revolution. More and more we have differentiated our lines of work, until what originally appeared to be a field in itself is now broken up, and the expert is he who spends a lifetime upon only one of the problems of a given field of knowledge. As William C. Gannett says: "The man of science, and to-day more than ever, if he would add to the world's knowledge, or even get a reputation, must be, in some one branch at least, a plodding specialist."

There is, however, to this argument another side that must be considered. While in an earlier day the work was of a general character, and the special phases of science as yet undeveloped, this very specialization of which we have been speaking has brought about a strong reaction. Constant touch with the special phases of work, concentration upon a comparatively narrow field of human interest, can not but have its effect upon the individual. This fact receives abundant exemplification constantly and illustrations need not be multiplied. Too often we find the technical expert or man of science a technical expert merely. If by nature he is narrow, his training in the schools only tends to enhance this narrowness. Of art or letters, music or drama, he knows little and cares

less. Business is a bore, history a closed book, and he has little in common with society and men and things. As the world develops he knows of this development, if at all, only from the standpoint of the growth of his own science. If he attempts aught outside his field, he fails.

This, then, is the anomaly. That while in the early days of applied science, to be an engineer implied a general knowledge of such principles of the subject as were known, the development of scientific and technical thought and appreciation and the birth of many courses produced extreme specialization. Hence we find the scientific man of to-day troubles himself, not so much with the broad phases of the subject as with a specific part. We have already reached the danger point and the *machine* engineer, the natural result of our present system, must soon be displaced by the *thinking* engineer. The artisan is to go down before the artist-artisan. Thought must take precedence over imitation. The necessity for a broader and more general knowledge upon which the specialty may with safety be constructed, is the argument here being presented.

With this main issue in mind, let us turn for a moment to the consideration of the number of high-grade institutions in this country wherein are offered courses of a technical nature.

A detailed study shows that out of forty-two state universities (the total number in the United States), thirty-six offer technical and engineering courses. Of other colleges and universities of a public, endowed or private character, there are sixty-three offering such courses, while there are forty-five special schools of technology and science; in all a total of one hundred and forty-four institutions offering technological courses.

Of the thirty-six state universities offering these courses, six only may be classed

as of the first order. Six of the sixty-three additional colleges rank as first-class institutions, while fourteen of the forty-five special schools of technology are in class one. In this latter number, the Naval Academy at Annapolis and the Military Academy at West Point are included.

Of the six state universities mentioned, all offer courses in electrical, civil and mechanical engineering, three offer courses in architecture, five in chemical engineering, four in agriculture, three in sanitary, two in mining and three in railway engineering, two in metallurgical engineering, one in naval architecture, two in forestry, one in marine engineering, one in irrigation and one in ceramics.

The six additional colleges of public and private nature offer courses as follows: six in electrical, six in civil and five in mechanical engineering, three in architecture, three in chemical engineering, two in agriculture, two in sanitary, four in mining and three in railway engineering, one in metallurgical engineering, two in naval architecture, two in forestry, two in marine engineering and one in horticulture.

In the fourteen special schools of technology, we find nine offering courses in electrical, eight in civil and nine in mechanical engineering, five in architecture, three in agriculture, two in sanitary, five in mining, one in metallurgical and five in chemical engineering, one in forestry, one in railway engineering, one in naval architecture, one in horticulture and one in ceramics.

This gives us a total for the twenty-six educational institutions of twenty-one offering courses in electrical and twenty each in civil and mechanical engineering, eleven each in architecture and chemical engineering, nine in agriculture, seven in sanitary, eleven in mining, seven in railway and five in metallurgical engineering, four in naval architecture, five in forestry, three in ma-

rine engineering, two in horticulture, one in irrigation and three in ceramics.

The combined courses offered by state universities, other public and private colleges, and the special technical schools (one hundred and forty-four institutions) are as follows: ninety-one in electrical, one hundred and thirteen in civil and ninety-four in mechanical engineering, twenty in architecture, fifty-nine in agriculture, fourteen in sanitary, fifty-two in mining, four in marine, ten in metallurgical, thirty-four in chemical and seven in railway engineering, four in naval architecture, four in irrigation, nine in forestry, twelve in horticulture, five in textiles, and five in ceramics.

These facts show the meager opportunities offered for intensive technical work, especially in the light of our rapidly developing resources. The mere fact that there are one hundred and forty-four institutions where education of the character indicated may be had, is not at all an answer to the point made. In most of these institutions calling themselves colleges, and in many of which the traditional subjects are well taken care of, the equipment, the location, the general facilities and the character of the instruction given in technical lines are not such as to fit for leadership or for executive positions, or to equip for expert work, nor are the humanities always so taught as to develop richness of mind.

What has been said of the narrowing influences of courses of study in schools of technology of to-day, applies in greater or less measure to every such institution in the country. Even those of greatest reputation are not free from this criticism. Some of these colleges are breaking the bonds of tradition and are broadening their curricula. The fact remains, however, that if we are to equip, *not machines, but men*, if the product of the school is to be first a man and then an engineer, it follows that the conservative measures of the past must

be disregarded and that we must demand a more logical treatment of our technical college schedules.

That the training given in the technical college be not over narrow and restricted, to the science, mathematics, drawing and shop work must be added such of the humanities as experience may show to be essential. The graduate of an engineering college or of a school of technology frequently finds himself in possession of sufficient facts connected with his profession, but with a knowledge of the language he uses so inadequate as to seriously handicap him in pursuing his vocation. The business side of his education he also finds, when too late, has been sadly neglected. To adequately express oneself and to perfectly understand all business forms, such as papers of conveyance, deeds, bills of lading, etc., are matters to be ignorant of which is absolutely inexcusable. Details of common law, training in questions of national and political economy, of general history and of commercial geography are fundamentally essential.

Herein is where the failure is so often made. The specialist can perform the task allotted to him, he can construct the plant, install the equipment, but can go no further. The management of the enterprise, the business side of the project, he can not grasp. For this purpose a business man is required, and the latter, having no acquaintance with the technical features involved, makes failure of his administration. The engineer must be an executive engineer. His training must be such as to enable him to tie together the various specialties. He must understand accounting and know how to make proper apportionments; in other words, he must be familiar with the commercial phases of his profession; he must have a knowledge of business methods, of political and economic conditions, of the development of trade and in-

dustry. He must know thoroughly the commercial side of his problem.

But if technical courses are thus broadened, adjustment must be made somewhere. No more can be crowded into the four years now required for graduation from a technical or engineering school. Must, then, these additional lines of work be demanded of technical students, and if so, how shall the schedules be adjusted?

Three alternatives present themselves as partial answer to the last question. First, the lengthening of the professional course to five or six years, making it graduate in character and on a par with graduate or professional schools of medicine or law. Second, the adding of two years to the present high-school courses now preparing for advanced technical work, thus enabling students to enter the technical college upon a much better foundation than at present. Third, the elimination of the non-essentials from the present four years' courses, thus leaving more time for additional necessary work.

The argument advanced by advocates of the first method is that the four years of regular college work is not sufficient. That to be adequately trained implies ultimately the lengthening of the college course to five or six years. Each year brings a greater store of knowledge to be taught and with this additional knowledge comes the understanding that to push the man through his course is to start him on the road to inefficiency. Especially must those who are to be leaders, the "trail blazers," the executives, the experts, be given advantage of a longer course.

The claim is made that after eliminating the non-essentials there will not be sufficient time in which to present the subjects of the special line being pursued and such of the humanities or so-called culture subjects as were previously suggested. English alone must be granted considerable

time, as an appreciation of good literature, a taste for the best that has been written, is essential to growth, whoever the man and whatever his profession. The student who in school and regardless of his trend of thought, is not given the opportunity of putting himself on friendly terms with the best in literature, is being robbed of one of the tools most necessary to advancement, and an element of the greatest pleasure and profit. On the other hand, so much must be added each year, as the discoveries and developments in science are made, that these alone may more than compensate for the eliminations.

Considering the second point, it would seem that there are many and strong arguments in favor of the lengthening of the high-school course to six years, such arguments applying with equal force to both traditional and manual-training high schools. But the lengthening of the preparatory course implies at once one of three alternatives. (1) A six-year preparatory course, in which the subjects are of secondary grade, without regard to lengthening of the college course thereafter. (2) A six-year preparatory course wherein certain preliminary college work is taken up, the regular college course to be either two years or four years in length. (3) A six-year course to be followed by a six-year college course. These propositions will receive no extended consideration at this time.

If the proper equipment and courses could be supplied in the high school, the students had better spend six years therein, as many who seek the technical and engineering college are so immature as to be unable to adjust themselves to the changed atmosphere, and go down and out in the first few weeks of school. Many have not found their level on leaving high school and are not adapted to the work to which they aspire. At much less expense than at

foods and drugs are prepared, sold or offered for sale. This is in line with the recommendations of the State and National Food and Dairy Departments.

3. An amendment to the Water and Sewage Law was passed, revising the definition of sewage so as to include industrial wastes, and giving the Board of Health authority over the operation, as well as the installation of both old and new water plants and sewage systems, also, providing for investigations concerning purity of water supply and the pollution of streams.

4. A comprehensive and stringent Weights and Measures Law was passed, authorizing the inspectors of the Food and Drugs Department to be inspectors of weights and measures, and charging them to assist in the enforcement of the law.

5. There was passed what is believed to be an effective hotel inspection law, with special attention to fire escapes, sanitary conditions, cleanliness, disinfection of rooms and sanitary supervision over places where foods are prepared.

6. Four important laws were passed, looking toward tuberculosis control in the state. One of these laws requires compulsory confidential reports of all cases; another is intended to control tuberculosis in animals; another refers to spitting in public places; and a fourth appropriates \$10,000 a year for an educational campaign for the supervision and prevention of tuberculosis.

7. A law was passed revising the general health laws, pertaining to health officers, and among other things empowering the State Board of Health to remove a county health officer for neglecting, or refusing, to perform the duties of his office.

This legislation will add very much to the powers already possessed by the State Board of Health, and they will be able, to a greater extent than ever before, to contend effectively with disease.

E. H. S. BAILEY

IN OKLAHOMA

The following is from the *Oklahoma City Times* of April 23:

Despite the fact that all the business transacted by the board of regents of the Oklahoma Agricultural and Mechanical College at Stillwater in its meeting April 13 to 15, has been kept secret, the fact has leaked out that the board decided on a wholesale dismissal of instructors.

As a result of the dismissals many are declaring that the action was taken in order that firmer supporters of the Haskell state administration might be elevated to positions which carry good salaries.

It is known that ten of the instructors in the schools have received notice of their dismissals, and that the new selections of the board will soon be named for their places.

Among those who have been dismissed are:

George H. Holter, professor in chemistry, who has held his position in the school with credit for seventeen years.

O. M. Morris, professor in botany and horticulture, who is a graduate of the school, class of 1896 and who graduated in his specialties from Cornell in 1897.

E. E. Balcomb, who is in charge of the agricultural work, which the school provides for the common schools of the state. Professor Balcomb was appointed by the same board last year.

James W. Means, professor in mathematics.

R. Rosensteingel, assistant in electrical engineering.

C. Beathy, in charge of chemistry in the experiment station. He is one of the appointees of the present board.

J. F. Lawrence, instructor in mathematics.

R. P. Sauerhering, assistant in mechanical engineering.

H. S. Weatherby, assistant in chemistry.

Miss C. H. Snapp, instructor in English, one of the board's own appointees.

It is reported that the board of regents of the university has resolved to confer the degree of doctor of laws on Mr. Linebaugh, the regent, at whose request the notorious letter from the Rev. Mr. Morgan was written accusing members of the faculty of dancing and card playing. The board has passed the following resolutions:

WHEREAS, the University of Oklahoma belongs to all the people of the state and should be conducted in such a way that the humblest citizen can not justly criticize it or any member of the faculty, and

WHEREAS, a goodly number of our citizens very

seriously object to members of the faculty engaging in the public and indiscriminate dance and card parties;

Therefore, be it resolved by the board of Regents, in regular session in the city of Norman, April 2 and 3, 1909, that we request the members of the faculty of this university to refrain from these amusements during their connection with this university.

Resolved further, that the president of the university be requested to furnish each member of the faculty with a copy of this resolution.

**BUILDING FOR SCIENTIFIC, EDUCATIONAL,
PATRIOTIC AND OTHER ORGANIZA-
TIONS IN WASHINGTON**

At the meeting of the National Academy of Sciences on April 21, 1909, the question of the lack of proper accommodations in the Smithsonian building for the National Academy, the American Association for the Advancement of Science, and other national and local scientific organizations was brought up by the Secretary of the Smithsonian Institution.

Secretary Walcott explained that the headquarters of the National Academy, the American Association for the Advancement of Science and the American Historical Association are in the Smithsonian Institution building; that three other bodies have applied for space, but there is no more room available and there is no place in Washington available for large scientific gatherings, such as would come together at meetings of the American Association for the Advancement of Science, and scientific congresses on various subjects. There will be better facilities in the new National Museum building, but there will be inadequate facilities for large meetings and congresses. He then called attention to the memorial building proposed by the George Washington Memorial Association. The general scheme as outlined by the association is to erect a great memorial building to George Washington in recognition of his strong desire expressed in his farewell address: "Promote then, as an object of primary importance, institutions for the general diffusion of knowledge"; also, "the promotion of science and literature."

The memorial association circular states that the building

will be dedicated to the increase and diffusion of knowledge in all lines of human activity that will conduce to the advancement of the welfare of mankind.

The building is to be well located, attractive in appearance, practical in plan and construction, and of the most durable character. It is to be planned so as to furnish a home and gathering place for *National, Patriotic, Scientific, Educational, Literary and Art Organizations* that may need such accommodations, including the Washington Academy of Sciences and its sixteen affiliated societies. It will furnish a place where all the Patriotic Societies both north and south may testify to their love for the Father of this Country. The building will contain a great hall or auditorium and rooms for large congresses, such as the recent Tuberculosis Congress; rooms for small and large meetings; office rooms and students' research rooms.

Primarily the basis of this movement is a patriotic one. The nation needs a headquarters for its great national organizations engaged in bringing the people in closer touch with each other, in all that pertains to patriotism and increase of knowledge that will make better and stronger men and women, physically, mentally and morally.

All the national and local organizations mentioned may have their offices in the proposed building and be liable only for their personal expenses, as it is planned that an endowment fund for the maintenance of the building shall also be collected.

The George Washington Memorial Association has \$25,000 in its permanent fund and \$5,000 for expenses. It is planning to organize in every state through state chairmen and to obtain funds by contributions of one dollar or more.

The memorial association recently elected Mrs. Susan Whitney Dimock, of New York, president, and the following advisory council has been appointed: Hon. Elihu Root, President Ira Remsen, Professor H. Fairfield Osborn, General Horace Porter, President Chas. J. Dabney, Dr. Charles D. Walcott, Mr. Charles J. Bell.

Mr. Charles J. Bell is the trustee of the permanent fund.

It was further explained that the memorial association is not working under an agreement with any educational or other institution but that it desired the cooperation of all organizations and individuals interested in its purpose.

After full consideration the National Academy of Sciences unanimously adopted the following resolution:

Resolved, That the National Academy of Sciences give its approval to the general plan of the George Washington Memorial Association to collect funds for the purpose of erecting and maintaining in the city of Washington a building adapted for a meeting place of scientific organizations.

The Washington Academy of Sciences has had the matter under consideration for some time through its building committee. On April 20 its board of managers recommended active cooperation with the memorial association and at a meeting of the academy, April 24, the following resolutions were adopted:

Resolved, that, in the opinion of the Washington Academy of Sciences, the efforts of the George Washington Memorial Association to provide suitable facilities in the city of Washington for bringing together the national patriotic, scientific, educational, literary and art organizations that may need such accommodations, including the Washington Academy of Sciences and its affiliated societies, deserves commendation and support.

Resolved, that the academy considers it eminently desirable that we should commemorate the interest felt by our first president in science and the higher education, and that no better method can be found than to provide, in the city which bears his name, the capital of the nation, a suitable meeting place for all engaged in the advancement of the welfare of the human race.

Resolved, that the academy appoint a special committee to cooperate in this important movement by all practicable methods.

Resolved, that the academy recommends to each of the affiliated societies that it appoint a similar committee to cooperate with the committee of the academy.

The Washington Academy has appointed its building committee, Dr. George M. Kober, chairman, as its effective agency to take the matter up with the members of the academy

and affiliated societies and the citizens of Washington.

SCIENTIFIC NOTES AND NEWS

PROFESSOR GEORGE E. HALE, Mount Wilson; Professor Santiago Ramón y Cajal, Madrid; Professor Émile Picard, Paris, and Professor Hugo Kronecker, Berne, have been elected foreign members of the Royal Society.

THE following new members have been elected to the American Philosophical Society: Louis A. Bauer, William Howard Taft, Washington, D. C.; Marston Taylor Bogert, Hermon Carey Bumpus, Dr. Alexis Carrel, A. V. Williams Jackson, New York; Edwin Brant Frost, Williams Bay, Wis.; Robert Almer Harper, Charles Richard Van Hise, Madison, Wis.; William Herbert Hobbs, Victor Clarence Vaughan, Ann Arbor, Mich.; Abbott Lawrence Lowell, Boston; William Romaine Newbold, John Frederick Lewis, Charles Bingham Penrose, Philadelphia; Francis Darwin, Cambridge, England; Hermann Diels, Emil Fischer, Berlin; Friedrich Kohlrausch, Marburg; Wilhelm F. Ph. Pfeffer, Leipzig.

M. PIERRE TERMIER, professor of mineralogy in the Paris School of Mines, has been elected a member of the Paris Academy of Sciences in the place of the late M. Gaudry.

PROFESSOR WILHELM OSTWALD, the eminent chemist, has been awarded by the University of Christiania its first Cato M. Guldberg medal.

SUBSCRIPTIONS to the Charles W. Eliot fund have been received from about 2,050 graduates of Harvard University and others, and amount at this time to about \$130,000. The subscribers have sent subscriptions as follows: 858, \$5 and under; 500, \$10 to \$20; 418, \$25 to \$50; 189, \$100 to \$250; 58, \$250 to \$500; 31, \$1,000 to \$10,000. The committee hopes that the fund will amount to more than \$150,000 by May 10, when President Eliot retires. The subscriptions have been placed in the hands of trustees, to invest and hold for the benefit of President and Mrs. Eliot. The fund will eventually pass to Harvard University.

DR. EUGEN WOLF has been promoted to the directorship of the Senckenberg Museum of

Natural History at Frankfort, in succession to the late Dr. Roemer.

DR. PAUL POPPENHEIM has been appointed custodian in the Zoological Museum at Berlin.

MR. JOHN HEWITT, of Jesus College, Cambridge, has been appointed assistant for molluscs and fishes at the Transvaal Museum, Pretoria. For the last four years Mr. Hewitt has been curator of Rajah Brooke's Museum at Sarawak.

DR. RICHARD PRAGER, of Berlin, has been appointed head of the computing division, and Dr. Walter Zuerhellen, of Bonn, head of the astrophotographic department in the Observatory of Santiago de Chile.

DR. EDWARD R. WALTERS has been appointed director of the Department of Health and Charities at Pittsburgh.

PROFESSOR WILHELM HITTOFF, the eminent physicist of Munich, has celebrated his eighty-fifth birthday.

DR. H. GRENACHER, professor of zoology at Halle, has retired from active service.

PROFESSOR A. LAWRENCE ROTCH, director of the Blue Hill Observatory, has returned from attending the International Aeronautical Commission at Monte Carlo.

DR. MAXIME BÔCHER, professor of mathematics at Harvard University, expects to spend the coming academic year abroad.

PROFESSOR H. E. CRAMPTON, of Columbia University and the American Museum of Natural History, will take his fourth voyage to the Society Islands this summer. Later he will go by way of Cook's Islands to New Zealand and the Samoan group via the Tonga Islands. He will return by way of the Fiji Islands and Hawaii, arriving home in January, 1910.

THE advanced students of geology at the University of Wisconsin left on April 30 for a ten days' trip through the iron and copper districts of Wisconsin, Minnesota and Michigan. Accompanied by Professors C. K. Leith, E. C. Holden and A. N. Winchell, they will be joined en route by Professor More, of Chicago, and a group of Chicago students; by Professors Mansfield, Cline and Sauer, of Northwestern and their students; and by a member

of the Canadian Geological Survey, Mr. Collins, of Ottawa, Canada. Starting from Duluth, the party will go through Tower and the Vermilion range; Biwabik and the Mesabi range; Carlton, Minn.; Houghton, Mich.; Ishpeming and the Marquette district, returning to Madison May 10.

PROFESSOR WM. A. LOCY, of Northwestern University, delivered the principal address before the Iowa State Academy of Science at Iowa City on the evening of April 30. His subject was "The Service of Zoology to Intellectual Progress."

DR. ALEXANDER GRAHAM BELL was announced to read on the evening of May 7 before the American Philosophical Society a paper on "Aerial Locomotion."

PROFESSOR WALTER R. CRANE, of the Pennsylvania State College, will read a paper on "The Use of Concrete in Mine Support" before the Institution of Mining Engineers meeting in London on May 28.

PROFESSOR GEORGE B. FRANKFORTER, dean of the college of chemistry at the University of Minnesota, lectured at the University of Wisconsin on April 30 on "Utilization of Waste Products from the Lumbering Industry."

PRESIDENT CHARLES R. VAN HISE, of the University of Wisconsin, has announced a course of instruction to be given next year in the geological department, on the conservation of natural resources. Dr. Van Hise's administrative duties have until now prevented his resuming teaching.

IN the fern herbarium of the New York Botanical Garden, which is now officially called the Underwood Fern Herbarium, a bronze tablet in his memory has been erected bearing the following inscription:

THE
UNDERWOOD FERN HERBARIUM
NAMED IN HONOR OF
LUCIEN MARCUS UNDERWOOD
1853-1907
CHAIRMAN OF THE SCIENTIFIC DIRECTORS
1901-1907

IN memory of the late Professor Mendeleef, it is proposed to establish in St. Petersburg a

Mendeleef Institution to contain chemical and physical laboratories and a museum.

DR. ALEXANDER KRAKAU, professor of electrochemistry at the University of St. Petersburg, died on March 29.

THE death is also announced of Professor F. E. Hulme, professor of mechanical drawing at King's College, London, and the author of several well-known books on wild flowers.

THE Society of German Chemists will hold its annual meeting at Frankfort from September 14 to 18.

UNDER the provisions of the program of administrative reform in preparation for constitutional government, the ministry of the Interior of the Chinese Empire has issued regulations governing the taking of a census of all Chinese, both at home and abroad. There will be a census of families and also of individuals. The former is to be completed in 1910 and the latter not later than 1912.

THE Academy of Science of St. Louis is bringing together an endowment fund of \$15,000, the income from which is to ensure continued publication of its long-established *Transactions*. To an invested fund of \$3,000 the council has added \$1,000 from the treasury and members have contributed an additional \$2,500. Of the remaining \$8,500, \$5,000 have already been subscribed.

OVER a ton and a quarter of rare earths has been presented to Professor Victor Lenher, of the department of chemistry of the University of Wisconsin, by the largest manufacturer of gas mantles in this country. The gift was made in recognition of the work on those substances which has been carried on for some years by Professor Lenher. The greatest quantity of monazite sand, which contains the rare earths in crude form, is found in North Carolina, the source of supply for all North American manufacture of gas mantles, as Brazil is the source for European manufacture. In the form of a by-product of gas mantle manufacture, the earths look like white flour, and it is in this form of oxalates that the 2,500 pounds given Professor Lenher

are stored in barrels in the chemistry building of the university. A number of graduate students at the university, under the direction of Professor Lenher, are devoting their efforts to various investigations of the rare earths. Three of these, Professor C. W. Stoddart, of the soils department of the agricultural college; Professor Raymond C. Benner, of the University of Arizona, who took his degree of master of arts at the University of Wisconsin in 1905; and Charles W. Hill, assistant in chemistry at the university, are at present making such investigations the subject of their dissertations for the doctor's degree.

ACCORDING to the *Westminster Gazette* the late Mr. John Murdock, who resided at Craiglockhart, in the county of Midlothian, by his will directed his trustees to employ the residue of his estate "in instituting and carrying on a scheme for the relief of indigent bachelors and widows, of whatever religious denomination or belief they may be, who have shown practical sympathy either as amateurs or professionals in the pursuit of science in any of its branches, whose lives have been characterized by sobriety, morality and industry, and who are not less than fifty-five years of age." The trustees notify that they are prepared to grant donations or pensions to persons "who have done something in the way of promoting or helping some branch of science" and who otherwise conform to the requirements of the trust.

WE are requested to state that the Royal Observatory of Belgium at Uccle is arranging to publish a list of the magnetic and seismological observatories of the world, together with a list of societies and reviews concerned with terrestrial magnetism, atmospheric electricity and seismology, and that information that will make these lists as complete as possible will be gladly received.

MR. J. H. GREGORY, '60, of Marblehead, has presented to Amherst College some 1,500 Indian implements, which include specimens from South Carolina, the Connecticut Valley and Marblehead. This collection consists largely of spears, arrowheads, hatchets and other implements of the southern Indians col-

lected by Mr. Gregory nearly fifty years ago, when he was a student at a theological seminary in South Carolina.

UNIVERSITY AND EDUCATIONAL NEWS

THE University of Washington, Seattle, will receive by appropriation of the state legislature the sum of \$678,000 for maintenance, for the biennium, 1909-11. Four permanent brick structures: an auditorium, a chemical laboratory, an engineering building, a power plant; and two semi-permanent structures: a library and forestry building will lapse to the university after being used by the Alaska-Yukon-Pacific Exposition, this summer.

MR. ANDREW CARNEGIE, in commemoration of twenty-five years' work in bacteriology and pathology done by the Carnegie Medical Laboratory of New York University, has given \$75,000 to the school. The money will be applied to the extension of the present Carnegie Laboratory building by an addition to it, which will face on First Avenue, the present building fronting on East Twenty-sixth street.

THE legislature of Nebraska in its recent session appropriated \$20,000 for the purchase of a new site in Omaha for the college of medicine of the University of Nebraska. The citizens of Omaha are to erect the buildings on the site thus obtained. The hall of mechanical engineering of the university is approaching completion and will be ready for occupancy in September. At a recent meeting of the regents the sum of \$50,000 was set aside for equipment. The regents are taking steps to locate two additional experiment sub-stations, as provided by the recent legislature. One of these is to be in the "Sandhill Region" of central Nebraska, and the other in the "Irrigation Region" of the western part of the state. They are contemplating considerable additions to the campus by the purchase of adjacent property. This has been made necessary by the present overcrowded condition of the campus. The tuition fees hitherto required of graduate students who are not residents of the state have been abolished.

THE Boston *Evening Transcript* states that plans are maturing for the establishment of a medical school in China. The promoters are Harvard men who intend to go to China at the expiration of their hospital appointments, having definite invitations from his excellency the viceroy of the Kiang Soo province. An endowment fund will be raised to be held by a board of trustees in this country, incorporated to direct the financial affairs of the institution. President Charles W. Eliot, of Harvard, has consented to serve as chairman of this board, and his associate trustees will be Dr. H. P. Walcott, Dr. A. T. Cabot, Dr. W. T. Councilman, Dr. W. B. Cannon, Dean H. A. Christian and Professor E. C. Moore. These are the men who intend to go: Drs. J. P. Leake, W. S. Whittemore, W. H. Hitlner, I. Hartshorn, C. C. Haskell, M. R. Edwards, A. L. Patch, A. M. Dunlap, G. P. Gaunt and C. A. Hedblom.

A DESPATCH from Denver to the daily papers says: "Differences between the members of the faculty and the board of trustees of Westminster University, Denver, Col., a Presbyterian institution, arising out of a general reduction of instructors' salaries, have resulted in the dismissal of President Joseph L. Weaver and the entire faculty. The reduction caused President Weaver and the faculty to bring suit for back pay, and the dismissal followed."

DR. WILLIAM A. SHANKLIN will be inaugurated as president of Wesleyan University on October 29. He will, however, assume the duties of the office after the close of the present academic year.

DR. CHARLES E. BESSEY, who has been for many years the dean of the industrial college of the University of Nebraska, has been promoted to be head dean of the university. He is chairman of the board of deans, and becomes the acting chancellor whenever the chancellor is absent or indisposed.

MR. C. T. BRUES, curator of invertebrate zoology in the Milwaukee Public Museum, Milwaukee, Wis., has been appointed instructor in economic entomology at the Bussey Institution of Harvard University.

DR. J. FRANK DANIEL, late at Johns Hopkins University, now working at the Pasteur Institute at Lille, France, has been appointed instructor in zoology at the University of Michigan, to succeed Dr. Dana B. Casteel.

DR. EMIL BOSE, of Danzig, has been appointed professor of physics in the University of La Plata.

PROFESSOR J. BAUSCHINGER has been appointed to succeed Professor E. Becker as professor of astronomy and director of the university observatory at Strassburg.

DR. EINAR HERTZSPRUNG, of Copenhagen, has been appointed associate professor of astronomy and astrophysics at Göttingen.

DISCUSSION AND CORRESPONDENCE

INDUSTRIAL FELLOWSHIPS

THE incidental reference made by Professor Kipping in his address before the British Association to a scheme of industrial fellowships which I have initiated in this university has led to so many inquiries from industrial chemists and to such general interest that I am compelled to present now its main outlines and present status rather than to wait, as I had intended, until its material results had determined fully its practicability. The scheme was initiated through an article entitled "Temporary Industrial Fellowships" which was published in the *North American Review* for May, 1907. This article was subsequently included as the last chapter in a book called "The Chemistry of Commerce" (Harper's). The scheme as then evolved has developed as I gained experience into something somewhat different; while it is essentially the same, I have found it practicable to claim on behalf of the university more advantages than I at first thought possible. Perhaps the present nature of the scheme is better exemplified in one of the later fellowship agreements, for example in Fellowship No. 7:

For the purpose of promoting the increase of useful knowledge, the University of Kansas accepts from the A. B. C. Glass Company, having head offices at New York, the foundation of a temporary industrial fellowship to be known as the A. B. C. Fellowship.

It is mutually understood and agreed that the conditions governing this fellowship shall be as follows:

The exclusive purpose of this fellowship is an investigation into the optical properties of glass in relation to its chemical constitution, to the furtherance of which the holder shall give his whole time and attention, with the exception of three hours a week, which he shall give to work of instruction in the chemical department.

The fellow shall be appointed by the chancellor of the university, the director of the chemical department and the professor of industrial chemistry; he shall have made previously a reputation in research; he shall be a member of the university, and shall pay all regular fees with the exception of fees for laboratory and supplies, for which his instruction shall be taken in lieu, unless in the opinion of the appointers his demands become excessive, in which case the donor shall be expected to reimburse the university; he shall work under the advice and direction of the professor of industrial chemistry; and he shall forward, periodically, through the professor of industrial chemistry, reports of the progress of his work to the A. B. C. Company.

For the support of this fellowship, which shall extend through a period of two years from the date of appointment of the fellow, the A. B. C. Glass Company agrees to pay fifteen hundred dollars (\$1500) per year, payable annually to the university on the date on which the fellow begins work at the university. This sum shall be paid by the university in monthly installments to the holder of the fellowship.

Any and all discoveries made by the fellow during the tenure of this fellowship shall become the property of the A. B. C. Glass Company, subject, however, to the payment by them to the fellow of ten (10) per cent. of the net profits, to be commuted at the desire of either party through the arbitration provided for herein, arising from such discoveries, it being understood that the fellow shall be regarded as the inventor. At any time during the tenure of his fellowship the holder shall, at the option of the donor, take out patents at the expense of the donor on condition that at the time of making application therefor he shall assign his right to the donor under the conditions of this agreement. At or before the expiration of the fellowship, the business services of the fellow may be secured by the A. B. C. Glass Company for a term of three years on condition that the terms of such services are satisfactory to both parties at interest.

In the event of any disagreement between the donor and holder of this fellowship, it is understood and agreed that the chancellor of the university, or one whom he may appoint, shall act, as arbiter as to all matters of fact, that his decisions shall be binding upon the parties at issue, and that they shall obtain such decision before having recourse to the courts.

It is also understood and agreed that during the tenure of this fellowship the holder may publish such results of his investigation as do not, in the opinion of the company, injure its interests, and that on the expiration of the fellowship the holder thereof shall have completed a comprehensive monograph on the subject of his research, containing both what he and others have been able to discover. A copy of the monograph shall be forwarded to the A. B. C. Company, and a copy shall be signed and placed in the archives of the university until the expiration of three years from that date, when the university shall be at liberty to publish it for the use and benefit of the people.

Signed on behalf of the University of Kansas.

Date

Signed on behalf of the A. B. C. Glass Company.

Date

There have been so far accepted by the university the following fellowships:

1. An Investigation into the Chemistry of Laundering, having for its object an improvement which will save in some measure laundered fabrics. It yields \$500 a year, together with 10 per cent. of the net profits.

2. A Search for a New Diastase. The present source of the best diastase is expensive. The investigation has as a matter of fact developed into an attempt to make a new fodder upon scientific principles. It yields \$500 a year and, under the original agreement, 10 per cent. of the gross proceeds for three years.

3. An Attempt to Utilize the Constituents of Waste Buttermilk, which, at present, in butter factories goes down the drains. These constituents, which it is desirable to conserve, are primarily caseine, and secondarily, lactic acid and sugar of milk. The fellowship yields \$500 a year and ten per cent. of the net profits.

4. An Investigation into the Chemistry of Baking. This investigation was established by the National Association of Master Bakers, with the object not only of improving the chemistry of bread, but, as well, of providing for the asso-

ciation a trained expert upon whom they could afterwards rely. It yields \$500 a year, together with a lump sum to be settled by arbitration, if necessary.

5. An Investigation into the Constituents of Crude Petroleum. I can not with propriety state the precise object of this investigation. The fellowship yields \$1,000 a year and 10 per cent. of the net profits.

6. An Attempt to Improve the Enamel upon the Enamel-lined Steel Tanks used in all kinds of chemical operations on a large scale. This fellowship was established by the largest manufacturer of these tanks in the world. It yields \$1,300 a year, together with an additional consideration to be decided upon, for the service rendered, by the chancellor of the university or one whom he may appoint.

7. An Investigation into the Relation between the Optical Properties of Glass and Its Chemical Constitution. This fellowship yields \$1,500 a year and 10 per cent. of the net profits.

8. The Discovery of New Utilities for Portland Cement and of Improvements in Its Manufacture. This fellowship yields \$1,500 a year and a large additional consideration dependent upon success.

The fellows for Fellowships Nos. 7 and 8 have not yet been selected. In addition to the foregoing fellowships there are certain others assured but not yet established:

9. An Investigation into Certain Glands of Deep-sea Mammals. It yields \$1,500 a year and an additional consideration to be decided upon by arbitration. This fellowship is to be a benefaction.

10. The Discovery of New Utilities for Oxone. It yields \$2,000 a year and 10 per cent. of the net profits.

The tenure of all fellowships is two years.

It is regrettable that in accordance with the terms of the agreement, it is impossible to publish at this time the results so far obtained. It may be said, however, that the progress of the fellows has been gratifying. It is significant in this connection that Fellowship No. 1, which expires shortly, is to be continued at *double the value* for three months, at the end of which time the donors will either take the fellow and his process into the factory or they will continue his fellowship through a third year at the increased amount; while with Fellowship No. 2 the donors have already indi-

cated their intention to continue it throughout a third year; the progress of the others has exceeded that of the first two and has surpassed expectations.

Most of these fellowships have arisen through letters of inquiry from the various companies. I have not gone out seeking fellowships in general. Had I done so it is not unreasonable to suppose that by this time there might have been from thirty to fifty. Owing to the fact that these fellowships have no relation to ordinary fellowships and that the scheme is essentially a new one, it has been deemed advisable to establish them at intervals. Proceeding in this way, and learning as one went, the scheme has undergone a natural and advantageous development. The degree to which it has been systematized, its effect upon the chemical department, the results of the relations of the different researches and researchers to one another, and the wholly unexpected interactional relation of the donating companies to one another I shall reserve for a future communication. While it should be said that as yet this scheme of industrial fellowships is wholly experimental and tentative, it ought also to be said that the two years' experience has not shown that it is any other than a sane and practical relation between the university and industry to the advantage of all concerned.

ELEMENTARY EMBRYOLOGY COURSES

THE publication of Professor Lillie's "Development of the Chick," and the excellent character of his treatment of the subject, suggests comment upon the custom of using the chick for introducing students to embryology. Since the days of von Baer and before, the chick has been used for embryological study more than any other form. This has probably been due in part to its familiarity and to the ease of obtaining embryos of any desired age. Foster and Balfour's very valuable, though poorly written, "Elements of Embryology," based on the chick, for so long the only avail-

able text-book for immature students, fastened more firmly the custom of using the chick in introductory embryological courses. Now comes Lillie's fine treatment of the same subject, which is likely to establish the chick in almost undisputed possession of these courses.

Chick embryos are easy to obtain and easy to manipulate and much has been written about them; they also have decided resemblance to human embryos. Yet in spite of these advantages I can not but feel that chick embryos are peculiarly ill-adapted to the use of students beginning the study of embryology. The embryo chick is a highly specialized form adapted to a very peculiar environment within an egg shell and still further distorted from the general vertebrate type by the presence of the huge yolk mass. These special adaptations are of great interest, but it has been my experience that they assume an undue prominence in the minds of students and prevent their readily grasping the general phenomena of development of vertebrates, unless some less specialized form, as for example, the frog, has first been studied.

The first three years I taught elementary embryology we began with the chick and used it chiefly, if not exclusively. Since then, each year, after a brief consideration of the cell, its organs, and its behavior in mitosis, and a rapid survey of cleavage and gastrulation in half a dozen forms, we have taken up the embryology of the frog, using Marshall's "Vertebrate Embryology," modified and supplemented, of course, by the lectures. The laboratory work has covered the same ground as the classroom work. After completing the study of organology in the frog, two weeks to four have been given to the chick and two or three lectures to comparisons with the development of mammalia.

The point I would like to emphasize is that I have found that the students in these later courses got a far better grasp of the embryology of the chick in two weeks' study following careful work upon the frog, than they ever succeeded in obtaining when they began with the chick and devoted all the time to this subject, and of course they got a far more adequate conception of the embryology of verte-

brates. The difference in the results obtained by the two methods has been so great that I could not be induced to return to the former method. The course of the second type has, in its results, utterly outclassed that of the first sort at all points, even in pure training in observation, for observation must include a conception of the adaptations in the phenomena observed. Even students who plan to study medicine are, I am sure, far better prepared to study with intelligence human embryology than if they had given their attention wholly or chiefly to amniote embryos in which the space relations of the organs are so distorted by secondary influences.

Material for the elementary cytological work and the study of cleavage and gastrulation is easy to prepare and also can readily be purchased, and there is no difficulty, of course, in obtaining frog embryos and larvæ. The yolk in the earlier embryos necessitates careful work in preparing sections, but, by avoiding absolute alcohol and by using an oil that does not make the yolk too brittle, good preparations are readily obtained. The labor of preparing sections of frog embryos and larvæ seems no greater than that of preparing chick sections. At any rate, the labor is not such as to lead one, in order to avoid it, to choose less instructive material for study.

Perhaps no clearer text-book has ever been written than Marshall's "Vertebrate Embryology." In spite of some inaccuracies, and of not being up to date, it is still usable, but its cost is considerable, and it contains more than most introductory embryological courses can cover. Holmes's volume, "Biology of the Frog," gives insufficient treatment to the embryology, and Marshall's little book, "The Frog," is no more adequate on this side. Morgan's "Development of the Frog's Egg" is not adapted for an introductory embryological course. We greatly need an embryology of the frog. A revision of Marshall's chapters on this subject, and their publication as a separate volume would well meet this need. Were there such a volume obtainable, one would not fear harm from the publication of Lillie's "Development of the Chick," for courses of each type would then have a satis-

factory text-book and an unbiased choice would be possible; but under present conditions one does fear that the very excellence of Lillie's book will serve to perpetuate an unfortunate tradition and will delay the general coming of embryological courses that are a better preparation for general morphological study.

M. M. METCALF

THE COUNTRY BOY AGAIN

IN SCIENCE, February 12, in discussing industrial education, I made the statement that with only 29 per cent. of our population actually living on the farm, with miserably poor school facilities as compared with our city population, this 29 per cent. furnishes about 70 per cent. of the leaders in every phase of activity in this country. This statement was quoted from memory and was in error to the extent that I should have said 29 millions of our population instead of 29 per cent. Dr. Frederick Adams Woods, in SCIENCE, April 9, quotes this statement and adds some criticisms.

First, I want to assure Dr. Woods that I appreciate very fully the magnificent work he did in his study of heredity in royalty. It fell to my lot to review Dr. Woods's book, and I found it one of the most interesting treatises on heredity we have. He has demonstrated, I think, beyond cavil, that "native ability and natural impulses of human beings are as much a matter of heredity as are any physical characteristics."

The above quotation is from my review of Dr. Woods's paper in my article on Mendel's law, which will appear soon in Volume V. of the American Breeders' Association. In that review I say further:

Prodigious effort has been made by the human race to better its condition but this effort has been wholly in the direction of improving the environment. While Dr. Woods has shown that it is really an unimportant factor in determining natural impulses and native ability, it is true that when environment is unfavorable it may prevent the development of natural tendencies or may warp them, and it may also result in great

natural ability remaining practically useless for a lack of the implements which a full development of intellectual power would place in its hands. But improving the environment does not from generation to generation give better material for our schools to work on.

I have only one criticism of Dr. Woods's reasoning. In studying heredity in royalty he purposely chose this class because it could be assumed that their characters were formed under the most uniform environment, which purpose was of course entirely legitimate. But it must be remembered that this environment is the best possible for the development of character and ability. It would be gratifying to me to see Dr. Woods make a similar study of some class of human beings subjected to an unfavorable environment. I believe he would find, as I have stated above, that even in that class native ability and natural impulses would prove to be purely a matter of heredity; but that character and actual ability would be found to be profoundly modified by environment. In fact, the whole experience of the human race speaks for this assumption. If the opposite were true, then why should the state go to the expense of maintaining schools, for a man's effectiveness would not depend on his environment, but upon his inheritance.

I have a further criticism to offer of Dr. Woods's article in *SCIENCE*. In the first place, the men listed in "Who's Who in America" do not represent leaders, although they include leaders. Dr. Woods's own figures prove the effect of environment as against heredity. For instance: under the initial A he finds 29.6 per cent. of city born individuals instead of the 16.1 per cent. expected on the basis of population. This merely shows that of the men in "Who's Who in America," those who have had the best opportunities have done best. "Who's Who in America" lists those men who have done something of note. I am inclined to believe that fully half of these men owe their success to their opportunities. They are not leaders, though they are competent workers, and they are not the type of men I had in mind in my previous article.

Census statistics do not easily lend them-

selves to the determination of the proportion of our population who actually live on farms. In rural population they include cities of considerable size. It has been said that "God made man, man made the cities, and the Devil made the country village." I have no way of ascertaining how many of the men who are distinctly leaders in this country were actually brought up on the farm. I am inclined to believe that the conditions in country villages and small towns are less favorable for the development of character than those on the farm or those in great cities.

I have not had time to secure extensive statistics on the birth-place of men who have been and are leaders in the various lines of activity in this country. In my previous article I merely repeated a statement I have heard frequently, and which I had never heard challenged. From the best statistics I can secure, about 36 per cent. of our population actually live on the farm at the present time. Of the 25 presidents of the United States, 23 of them were country bred, or were brought up under what the census terms rural conditions, only our present president and his immediate predecessor having been brought up in the city, so far as a hasty glance at history and biography reveals. This is 92 per cent. of the total, and there is no question that these men have been leaders. Of the present membership of the United States senate, in so far as the congressional directory reveals the facts, 70.5 per cent. are country bred. The statistics for the house of representatives are not so conclusive. The fact that many congressional districts are wholly city districts while others are wholly country districts vitiate the statistics for that branch of congress, so far as our purpose is concerned.

I hope to be able, in the not distant future, to present other statistics bearing on this question. I believe, however, that when we consider the fact that our country schools have always been vastly inferior to our city schools, the few data given above show that there is something in farm life, during the first few years of the boy's training, that tends more nearly to give normal expression to his hereditary talents and impulses than do con-

ditions of city or village life. The matter must rest here until further statistics are available.

W. J. SPILLMAN

U. S. DEPARTMENT OF AGRICULTURE

THE RELATION OF THE METER AND THE YARD

TO THE EDITOR OF SCIENCE: It is a matter of astonishment to me that so many men, authors of scientific books, are ignorant of the fact that the relation between the meter and the yard is in the United States fixed by law, viz., 1 meter = 39.37 inches. In England the established relation is 1 meter = 39.370113 inches. As examples, see "Fortie's Electrical Engineers' Handbook," 5th Ed., 1908, p. 1500, and "Eggleston's Tables of Weights and Measures," 4th Ed., 1900, p. viii, in both of which the archaic, inherited necessary relation, 1 meter = 39.37079 inches is adopted. In trade catalogues an error of this sort is not so serious and is occasionally made; but in a scientific publication it is unpardonable.

MARSHALL D. EWELL

SCIENTIFIC BOOKS

Primitive Secret Societies. A Study in Early Politics and Religion. By HUTTON WEBSTER, Ph.D., Professor of Sociology and Anthropology in the University of Nebraska. New York, The Macmillan Co. 1908. Pp. xiii + 227.

This book, which has served in its original form as a thesis for the doctorate in political science at Harvard University, treats, in eleven chapters, of the men's house, the puberty institution, the secret rites, the training of the novice, the power of the elders, development of tribal societies, functions of tribal societies, decline of tribal societies, the clan ceremonies, magical fraternities, diffusion of initiation ceremonies. The author's studies were concluded before he became acquainted with the late Dr. Heinrich Schurtz's "*Altersklassen und Männerbünde*" (Berlin, 1902), of which, however, he was able to make some use in the present monograph. The book of Schurtz, rather *tendenciös* in places and somewhat marred by a philological appendix, but, nevertheless, an interesting and valuable

summary of facts, was preceded by Boas's (1895-7) investigations of the social organization and secret societies of the Indian tribes of the North Pacific coast (particularly the Kwakiutl), which still remain the best source of information for that region, as yet not adequately used by any authority. For the Plains tribes we have recent investigations by Wissler, Dorsey, Fletcher, Kroeber, and for the Pueblos Indians, those of Fewkes, etc. The material in Dr. Webster's book, as is the case with all others dealing generally with the topic of secret societies and ceremonies, is preponderatingly Australasian, Indonesian and African, though at pages 15-19 ("men's house"), 131-134 (age-societies), 147-159 (clan-ceremonies) and 176-190 (magical fraternities), the aborigines of the new world receive particular attention.

The author begins with the "men's house," described as follows:

The men's house is usually the largest building in a tribal settlement. It belongs in common to the villagers; it serves as council-chamber and town hall, as a guest-house for strangers, and as the sleeping resort of the men. Frequently seats in the house are assigned to elders and other leading individuals according to their dignity and importance. Here the more precious belongings of the community, such as trophies taken in war or in the chase, and religious emblems of various sorts, are preserved. Within its precincts, women and children, and men not fully initiated members of the tribe, seldom or never enter. When marriage and exclusive possession of a woman do not follow immediately upon initiation into the tribe, the institution of the men's house becomes an effective restraint upon the sexual proclivities of the unmarried youth. It then serves as a club-house for the bachelors, whose residence within it may be regarded as a perpetuation of that formal seclusion of the lads from women, which it is the purpose of the initiation ceremonies in the first place to accomplish. Such communal living on the part of the young men is a visible token of their separation from the narrow circle of the family, and of their introduction to the duties and responsibilities of tribal life. The existence of such an institution emphasizes the fact that a settled family life with a private abode is the privilege of the older men, who alone have marital rights over the women of the tribe. For promiscuity,

either before or after marriage, is the exception among primitive peoples, who attempt not only to regulate by complicated and rigorous marriage systems the sexual desires of those who are competent to marry, but actually to prevent any intercourse at all of those who are not fully initiated members of the community (p. 1).

As men's houses, or as survivals thereof are cited the *eramo* of New Guinea, the Dyak *pangah*, the Formosan *palangkan*, the Dravidian (Oraon) *dhumkuria*, the Naga *morang*, the Polynesian *marae*, the Bechuana *khotla*, the Unyamwezi *iwanza*, the Bororó (Brazil) *baito*, the Pueblo *kiva*, the Hupa *tsikyuw*, the Eskimo *kashim*, etc., but the unitary origin and service of all these is by no means demonstrated. According to Dr. Webster, "the presence in a primitive community of the men's house in any one of its numerous forms points strongly to the existence, now, or in the past, of secret initiation ceremonies." With some tribes the men's house "is used as the center of the puberty initiation ceremonies," and, "with the development of secret societies, replacing the earlier tribal puberty institutions, the men's house frequently becomes the seat of these organizations and forms the secret 'lodge.'" The men's house thus "serves a general purpose as the center of the civil, religious and social life of the tribe, and a special purpose as the abode of unmarried males." The first secret society is thus a "clan," which excludes women and boys. Next comes, apparently, the "puberty institution" with other subdivisions based on age and the recognition of its value to the community. Here the elders are in control and secret rites for the initiation of young men, their subjection to ordeals, and instruction in tribal wisdom and obedience (often in long periods of seclusion) appear to be "the characteristically social feature of primitive life," and "these mysteries, as the most conservative of primitive customs, provide an effective means of social control." These initiation ceremonies are tribal and communal machinery organized and conducted by the elders which can no longer operate when obedience to the tribes is replaced by obedience to the chief, and

"initiation ceremonies, such as have been studied, retain their democratic and tribal aspects only in societies which have not yet emerged from that primitive stage in which all social control is in the hands of the tribal elders" (p. 75). And, "with increasing social progress, the powers of control are gradually shifted from the elders to the chiefs, and tribal societies charged with important political and judicial functions arise on the basis of the original puberty organizations." The new order of things brings with it limited membership, "degrees," "lodges," elaborate paraphernalia of mystery, etc. Secret societies may now "represent the most primitive movement towards the establishment of law and order," or may "embody the inner religious life of the tribe" and gather strength "from the pretended association of their members with the spirits and ghosts of the dead." Tribal secret societies arising through "a process of gradual shrinkage of the original puberty institution, in which, after initiation, all men of the tribe are members," often survive as "organizations of priests and shamans, in whose charge are the various dramatic and magical rites of the tribe" (p. 135). In connection with his argument at this point Professor Webster holds that "among the northwest tribes (of American Indians) the clan organization is in decay and secret fraternities in initial stages of development," and "among the tribes of the southwest the totemic clans have broken down to be replaced by numerous and well-developed magical fraternities," both statements open to serious objections, as to fact and also as to theory. In the rites of these magical fraternities too many "survivals of primitive puberty rites" are seen by the author; and the diffusion of such rites is perhaps not so extensive as he believes. The list of tribes possessing no puberty rites and, consequently, none of the social paraphernalia held to be developed from them would be of interest here. It is quite evident that even in primitive society there is something more than sex. It would be worth while knowing, as a contrast to the "men's house," how widespread and how "primitive," *s. g.*, is the

maloca, a characteristic house of the Indians of northwestern Brazil, recently described by Dr. Koch-Grünberg.¹ The *maloca's* inhabitants are mostly one family, often an old couple with their grown-up sons and their families, etc. They number from 10 to 100 individuals, all under the same roof, and the author testifies to the good-behavior and morality of them all. Owing to the practise of extra-tribal marriage it frequently happens that women speaking absolutely distinct languages live in the same *maloca*. In it also are celebrated some of the great dance-festivals. The sick are cared for within its walls and the dead interred beneath the floor. The *maloca* is thus as far removed from the "men's house," as can well be imagined, and it exists among very primitive folk. This serves to illustrate the relativity of some of the ideas and institutions involved in the discussion of "primitive politics and religion." The esoteric element, though often notable and significant, has probably been overestimated in the history of human evolution.

In the opinion of the reviewer, the author will add to the value of his interesting book if, in a second edition, he makes an index and presents the bibliography in alphabetical order at the close and not as now in rather distracting though instructive footnotes.

ALEXANDER F. CHAMBERLAIN

CLARK UNIVERSITY,
WORCESTER, MASS.

Unsere Ahnenreihe. (Progonotaxis hominis.) Kritische Studien über phyletische Anthropologie. By ERNST HAECKEL. Jena, Gustav Fischer. 1908.

This quarto memoir of fifty-seven pages is, as its title-page indicates, a Festschrift in honor of the 350th anniversary of the Thuringian University at Jena, the celebration of which was made the occasion for the transference to the university of the "Phyletic Museum" founded by Professor Haeckel, "das erste Museum für Entwicklungslehre." The occasion was naturally propitious for a

¹ "Das Haus bei den Indianern Nordwestbrasilien," *Archiv für Anthropologie*, 1908, N. F., VII., 37-50.

consideration of that most interesting of all phyletic problems, the descent of man, and in the memoir before us Professor Haeckel has traced the various steps, as he conceives them, through which the line of ascent has passed from the moners to man. What is presented is, however, almost entirely a repetition of the material to be found in chapters XIX.-XXIII. of the "Evolution of Man," a work that has already been noticed in these columns,¹ and it is not until toward the close of the memoir that any new contribution to the question is to be found. Here, after some notice of *Pithecanthropus* as the "missing link" and a paragraph devoted to *Homo primigenius*, under which term are included the Neander, Spy and Krapina men, one finds a description of the most striking peculiarities of a skull of an Australian aborigine from Queensland, which Professor Haeckel regards as "the most remarkable human skull of the many thousand with which anthropology has concerned itself." He considers it as representing a reversion to the ancestral *Homo primigenius*, and for this reason creates for its original possessor the species *Homo palinander* (= *Homo primigenius recens! -atavus?*).

Five plates, giving views of the norma frontalis, occipitalis, verticalis, basalis and lateralis of this skull, together with those of *Homo sapiens (germanus)*, *Anthropithecus niger*, *Hylobates mulleri* and *Cynocephalus mormon*, complete the memoir and are beautiful examples of photographic reproduction. A sixth plate, the series of mammalian embryos familiar to all readers of Haeckel's works, hardly requires comment.

It may be remarked, however, that the author's predilection for the coinage of new terms in order to give definiteness to his concepts, finds expression in the memoir, but hardly with as happy results as usual. For the terms *Homo neander*, *H. spyander* and *H. krapinander*, consistent as they are orthographically, are certainly most inconsistent etymologically.

J. P. McM.

¹ SCIENCE, N. S., Vol. XXII., 1905.

Introduction to the Rarer Elements. By PHILIP E. BROWNING, Ph.D., Assistant Professor of Chemistry, Yale University. Second edition, thoroughly revised. New York, John Wiley & Sons. 1908. Pp. x + 207, 2 plates.

The first edition of this book was reviewed in these columns in 1903.¹ After five years it has been revised, much new material being added. This is especially the case in regard to the radio-elements, the excellent chapter upon that topic being contributed by Professor Boltwood, a colleague of the author.

While the book is teeming with information, it does not pretend to be a compendium. However, one feels the lack of proportion when he observes that forty-nine double chlorides of cesium (p. 11) are mentioned and only one oxide of rubidium is named. The statement is made (p. 63) that metallic praseodymium and neodidymium have not been separated. Mpthmann accomplished this very cleverly several years ago and his method has been applied successfully in the reviewer's laboratory. Good crystals of metallic thorium have also been obtained by another method, namely, reduction by aluminium, published in the Year Book of the Carnegie Institution. It is not mentioned. A satisfactory method for separating zirconium and aluminium (p. 78) published fifteen years ago is not incorporated. Nor is the only good method for separating zirconium and titanium (by hydrogen dioxide) given. The chapter on the uses of the rarer elements is in much need of revision. The recent work on scandium is not included.

The colored plate of the spectra is a good illustration of the printer's art, but the small plate on the absorption spectra is poorly chosen, in fact, is incorrect. Additional plates would be helpful, as well as a general discussion of some of the principles involved in the fractionation of these "complexes of elemental matter," as Crookes put it. There is an index, but it is inadequate.

The book must have served a good purpose and every library of chemical works should have a copy, for the term "rare earth" does

¹ SCIENCE, N. S., XVIII., 497.

not frighten teacher or student quite as badly as formerly. This is due in large part to a book of such rightness of purpose as is this one.

CHAS. BASKERVILLE

COLLEGE CITY OF NEW YORK

SCIENTIFIC JOURNALS AND ARTICLES

The American Museum Journal for March contains the following articles: "The Darwin Celebration," with views of the bust of Darwin presented to the museum by the New York Academy of Sciences; "New Habitat Groups of North American Birds," six in all, with an illustration of each. These groups mark the highest point reached in presenting to the public an accurate idea of the bird life of various parts of our country; they have been made possible by the liberality of a number of friends of the museum and of the public. A notice of "The Annual Meeting of the Trustees" notes that the present endowment fund is \$2,048,156, and that last year the museum expended \$115,488, and the city \$159,930. There is a letter from Mr. Stefansson, on "The Stefansson-Anderson Arctic Expedition," and an account of "Recent Purchases of Fossil Vertebrates."

The Museums Journal of Great Britain for February has an article on the "Victoria and Albert Museum," reviewing the recent report on its rearrangement, classification of its material, relations of the national museums to one another, and on the general policy of the institution. Most interesting is the account given by Rev. J. S. Whitewright of "Pioneer Museum Work in China." The models, diagrams and maps, many of them large and elaborate, were made on the spot by Chinese artisans. The number of visitors—there were 69,745 in thirty-six days—shows the success of the work. Robert Standen tells how to make and use "Glue and Turpentine Cement for Alcoholic Mounts." There are the customary reviews and notes.

SPECIAL ARTICLES

A LITTER OF HYBRID DOGS

SEVERAL years ago the writer had the opportunity of observing the results of a cross be-

tween two "thoroughbred" dogs. The breeds were sharply contrasted in many characters and the results were so striking that an effort has been made to collect the data regarding the offspring, from the owner of the dogs. While the data thus obtained are of course very incomplete, they are considered of sufficient interest to merit a brief record. Prac-

tically nothing of a scientific character appears to have been done in this very interesting field for students of heredity.

The mother of the cross in question was an Old English Bobtailed Sheep Dog and the father a Scotch Collie so-called. Both were typical specimens of their respective breeds. The dogs were accompanied by a guarantee

	Mother	Father	Pup No. 1	Pup No. 2	Pup No. 3	Pup No. 4	Pup No. 5	Pup No. 6
Color.	Grizzly throughout except white breast.	Black and tan, breast white, body jet-black, legs tan from feet to first joint.	Black, breast and paws white.	Blue-gray throughout, except white breast and paws.	Body black, legs light tan.	Body black, legs light tan.	Dark brown, except white breast.	Large patches of white and light yellow over whole body. Fore legs white, hind yellow.
Character of coat.	Long and shaggy over whole body, including eyes, face and legs.	Heavy and wavy.	Shaggy, hanging over eyes, face and legs (mother) but very wavy (father).	Shaggy, long, wavy hair over whole body, including eyes, face and legs.	Hair short and smooth.	Hair short and smooth.	Thick, wavy hair over whole body, including face and legs.	Hair short and smooth.
Tail.	None. No projecting bone.	Long and bushy, jet-black.	About four inches long.	About four inches long.	About eight inches long.	About eight inches long.	Six inches long with a kink in the middle.	Long and bushy, yellow.
Eyes.	Dark brown.	Light brown.	Dark brown.	Dark brown.	Light brown.	Light brown.	Dark brown.	One wall eye, one light brown.
Disposition.	Very gentle and timid.	Playful and aggressive.	Gentle and timid (mother) but at times inclined to snap (father).	Very gentle.	Very aggressive.	Gentle.	Aggressive.	Very timid.
Legs and body.	Body long, legs long. Hind legs very short from feet to hock, but very long from hock to hip.	Legs ordinary length and shape.	Like mother.	Like mother.	Like father.	Like father.	Like mother.	Like father, but smaller.
Shape of head.	Like mother.	Like mother.	Like father.	Like father.	Like mother.	Like father, but smaller.
Sex.	Male.	Male. Like No. 1, except in color.	Male.	Female. Just like No. 3 except disposition.	Male.	Female.

that they were thoroughbred, and were brought from England to Nova Scotia by an English gentleman for the purpose of crossing them to produce a dog for farm purposes.

I had occasion to observe both dogs carefully for a considerable period, and I also owned one of the pups for several years. The pups were born in June, 1894. I am, of course, aware of the dangers of collecting *post facto* data and have therefore included here only such facts as I can verify with certainty from my own recollection. The data given under "legs and body" and "shape of head" are of course only general impressions of a probably more or less blended condition.

The accompanying table shows some of the contrasting characters in the parents and the offspring. The most striking contrasts are afforded by the color and character of the coats, the presence and absence of the tail, and its variability in the offspring, and by the dispositions, that of the mother being very gentle and timid, while the father had the aggressive collie disposition. The litter contained more than six pups, but these are the only ones which can now be sharply and definitely characterized. It is a noteworthy fact that several of them are in pairs which are very closely alike, differing markedly in only one character so far as observed. Numbers 1 and 2 were alike except in color, one having the general color of the mother, and the other that of the father but without any tan. Numbers 3 and 4 constituted another very clearly marked pair, differing widely from the others in many characters and yet so closely alike that they were scarcely distinguishable, except in their dispositions, which were quite unlike. This recalls some cases of identical human twins. These animals were not of the same sex, however.

In comparing the characters of the offspring with those of the parents it will be seen that in no character was there complete dominance of one parent in all the offspring. In coat color the father dominated in all but two, in one of which (No. 2) the color was that of the mother. The long, shaggy coat, covering the face and legs as well as the body, appeared in Nos. 1 and 2 of the offspring, except that the

effect of the wavy hair of the father was also more or less evident. In No. 5 the coat more nearly resembled the father, but in Nos. 3, 4 and 6 was quite unlike either parent, being short, smooth and sleek. The differences in eye color may not be significant, as the collies' eyes range from light to dark brown, and in the sheep dogs a wall eye is not uncommon and is considered typical of the breed.

The inheritance of the tail character is of considerable interest, showing as it does a range from the long bushy tail of the father to a condition approaching its complete absence as in the mother. The intermediate tail lengths can not be attributed wholly to inheritance from the father, however, for dogs with more or less of a tail are said to occur frequently in the pure sheep-dog breed. How the tailless condition originated appears to be unknown, although various statements and conjectures are made in dog books concerning this matter. Two breeds of bob-tailed collie, with tails 5-10 cm. long but otherwise in every particular like the collie, are recognized in certain parts of England¹ (II., p. 440). Walsh² says (p. 221):

Until within the last half-century sheep dogs without tails were exempt from taxation, it being supposed that no one would keep a tailless dog who could afford to pay the tax. As a consequence almost every sheep dog had its tail cut off, and owing to this cause the tailless sheep dog, still met with in some localities, is supposed to have arisen. . . . It is far more probable that the bob [in pointers] is derived from a cross with the bull dog, which is subject to the natural loss of tail in a greater or less degree, and was probably used to give courage to the pointer. . . . Usually these "bobs" [the old English sheep dog] are strongly made and symmetrical dogs, but without any definite type; they have frequently a tendency to the brindle colour, which favours the theory of the derivation of short tails from the bull dog though it cuts equally against a similar derivation in the pointers, in whom the brindle is absolutely

¹ "Dogs of All Nations," 2 vols., London, 1906, illustrated.

² Walsh, J. H., "The Dogs of the British Islands, etc.," 5th edition, London, 1886, pp. 292, illustrated.

unknown. Not being able to arrive at any definite type of the "bob-tail," I shall not attempt to describe him.

From this writer it would appear that the Old English Bob-tail is a recent, or at least variable and poorly characterized breed. Lee¹ states, however, that Reingle's picture in the "Sportsman's Cabinet," very early in the last century, is typical of the breed as at present known, showing that this breed has probably existed for at least a century. He further states that it is possibly older than the collie. The varieties in England and Scotland are said to be identical, except that the latter usually has a long tail, the reason attributed for this being that the owners have steadfastly refused to amputate it! It is stated that in England many of these dogs are born either without tails or with very short ones, pups with and without tails usually occurring in the same litter. The tails may be docked so that no one can tell that the animals were not born tailless. They are said to be jet-black at first with white markings, in a few weeks becoming "silvery-lilac."

This writer argues that the antiquity and concentration of the strain is shown by the fact that if there is a strain of this breed in such breeds as the retriever, lurcher or spaniel many generations back, a typical specimen will occasionally appear.

In the "Dogs of All Nations" already referred to, which is a standard authority on the good and the bad points in the various breeds of dogs, giving their characterization according to the various dog clubs and breeders, a black and tan or brindle coat is considered a fault in the Old English Bobtail breed (*l. c.*, II, p. 471).

Such remarkable diversity as here described in a single litter of offspring could not be accounted for by the effect of external conditions of development and must therefore be due to differences of some sort in the germ cells of either or both parental individuals. No one

¹ Lee, Rawdon B., "A History and Description of the Modern Dogs of Great Britain and Ireland (Non-sporting Division), etc.," London, 1899, pp. 428.

character is present in all the offspring to the exclusion of its homologue. There is a decided tendency in any given character for the offspring to "take after" one parent or the other, though in certain cases, as in the character of the hair in Nos. 3 and 4, there is a marked departure from either parent. This is perhaps the reappearance of a character derived from some cross in the ancestry of one of the breeds.

One further fact worthy of mention is the disposition of dog No. 1. I had him in my possession for several years and often observed the usually very subdued and timid behavior, and at times the sudden and unexpected change to the aggressive attitude of his father. It will be noted that some of the dogs inherited the aggressive disposition of their father and others the timid and gentle disposition of their mother.

UNIVERSITY OF CHICAGO,
April 2, 1909

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION E—GEOLOGY AND GEOGRAPHY

SECTION E, Geology and Geography, of the American Association for the Advancement of Science, met Monday morning, December 28, 1908, at Johns Hopkins University. The section organized at 11 A.M., immediately after the adjournment of the general meeting of the association. The first five papers of a Symposium on Correlation were given during the morning and afternoon sessions on Monday. This symposium was continued on Tuesday and Wednesday under the auspices of the Geological Society of America.

Professor J. P. Iddings, of Chicago, gave his vice-presidential address, "The Study of Igneous Rock," on Monday, at 2:30 P.M.¹

According to the custom for several years past, Section E adjourned Monday P.M., but its fellows and members were cordially invited to be present at the sessions of the Geological Society of America, December 29 to 31, 1908, and at those of the Association of American Geographers, January 1 and 2, 1909.

Following the dinner of the Geological Society of America on Wednesday evening there was a discussion of the relations that should obtain

¹ SCIENCE, Vol. XXIX., pp. 202-217.

between Section E and the Geological Society of America and the Association of American Geographers. This was done in order that the officers of the three geologic-geographic organizations may be able to plan future meetings for the reading of papers and for field excursions, so that the needs and wishes of all geologists and geographers may be met as fully as possible.

On Thursday evening, December 31, Dr. Albrecht Penck, professor of geography at Berlin University and Kaiser Wilhelm professor at Columbia University, delivered a public address on "Man, Climate and Soil," given under the auspices of the Association of American Geographers.

The Society of Vertebrate Paleontologists held its meeting during the week, an account of which has been given in *SCIENCE*.*

SYMPOSIUM ON CORRELATION

Monday, December 28

Pre-Cambrian.

C. R. Van Hise, "Principles of pre-Cambrian Correlation."

F. D. Adams, "The Basis of pre-Cambrian Correlation."

Discussion.

Early and Middle Paleozoic.

C. D. Walcott, "Evolution of Early Paleozoic Faunas in Relation to Their Environment."

Discussion.

A. W. Grabau, "Physical and Faunal Evolution of North America in the Late Ordovician, Silurian and Devonian Time."

Discussion.

Stuart Weller, "Correlation of Middle and Upper Devonian and Mississippian Faunas of North America."

Discussion.

Tuesday, December 29

Late Paleozoic.

G. H. Girty, "Physical and Faunal Changes of Pennsylvanian and Permian in North America."

David White, "The Upper Paleozoic Floras, Their Succession and Range."

Discussion.

Vertebrates.

S. W. Williston, "Environmental Relations of the Early Vertebrates."

H. F. Osborn, "Environment and Relations of the Tertiary Mammalia."

Discussion.

Tertiary and Quaternary.

F. H. Knowlton, "Succession and Range of Mesozoic and Tertiary Floras."

Discussion.

R. D. Salisbury, "Physical Geography of the Pleistocene with Special Reference to Conditions Bearing on Correlation."

D. T. MacDougal, "Origination of Self-generating Matter, and the Influence of Aridity on its Evolutionary Development."

Discussion.

T. C. Chamberlin, "Diastrophism as the Ultimate Basis of Correlation."

The following note on the symposium on correlation, was prepared by Mr. Willis, for the secretary's report of the Baltimore meeting:

In accordance with the announcement made in *SCIENCE*, December 18, 1908, a symposium on correlation was presented at the Baltimore meeting under the auspices of Section E and the Geological Society of America. The object proposed was a discussion of the physical and biological criteria of correlation, and the influences of the physical upon the biological. While most of the papers presented were mainly paleontological, there was generally throughout the papers and the discussions an undercurrent of thought with reference to this relation of cause to effect. In some cases decided emphasis was placed upon the relation of faunas and floras to environment.

Messrs. Van Hise and Adams presented two views concerning the criteria of correlation of the pre-Cambrian and the classifications which result from their application. Van Hise maintained the validity of the dual classification of the pre-Cambrian, and, after discussing the value of lithologic similarity, stratigraphic similarity and unconformities for matching strata, applied these methods to the North American pre-Cambrian with results which he has elsewhere published recently. Adams approached the problem as a part of the record of continental history and based a tentative classification of the pre-Cambrian upon possible parallel events in North

America and Eurasia. In discussion Van Hise pointed out the similarities between the two sets of conclusions.

The correlation of the major part of the Paleozoic was discussed by Messrs. Walcott, Grabau and Weller, whose papers comprised the period from Cambrian to Mississippian, inclusive. Walcott followed conservatively the lines of classification laid down in his earlier papers on the Cambrian of North America. He felt obliged by the state of investigations to confine his discussion largely to evidence afforded by the brachiopods and indicated that more elaborate conclusions might be suggested by a similar thorough study of the trilobites and other elements of the faunas. Grabau discussed the faunas and sediments of Ordovician, Silurian and early Devonian times, together with certain phases of the paleogeography and climatic conditions, especially of New York and Michigan. Weller stated that during Middle and Upper Devonian time the faunas of North America occupied three provinces, the eastern continental, interior continental and the western continental. The provincial conditions continued into early Mississippian time, but gave place to more cosmopolitan conditions through the development of the great Mississippian province, with sub-provinces east of the Cincinnati arch and also in the western part of the continent.

The late Paleozoic and early Mesozoic were discussed by Messrs. Girty, David White and Williston, with reference, respectively, to the invertebrate faunas, the floras and the vertebrates. Girty considered chiefly the relations of the Pennsylvanian and possible Permian faunas of North America, and their correlation with the Permian of Russia. White brought out the world-wide distribution of certain late Paleozoic floras and touched upon the paleogeographic relations essential to their distribution.

Williston was followed by Osborn, who discussed the Cenozoic vertebrates, and in the discussion of their two papers the value of vertebrate paleontology in its bearing upon former land connections was distinctly apparent.

In discussing the succession and distribution of the later Mesozoic invertebrates, Stanton considered late Jurassic, Lower Cretaceous and Upper Cretaceous faunas in their bearing upon the geography of those periods. A problem of peculiar difficulty is presented by the marked distinction which exists between the Lower Cretaceous fauna of the gulf region and that of the

Pacific coast, in spite of the fact that in Mexico a Pacific fauna invades the western margin of the province that was usually occupied by the gulf fauna. In order to explain these relations it appears to be necessary to recognize the probable existence of a southern extension of the land area of Arizona and its partial submergence first from the east and then from the west.

In discussing the conditions governing the distribution and evolution of Tertiary faunas, Dall emphasized the importance of temperature of marine waters and showed that in so far at least as Tertiary and existing faunas are concerned, it formed the dominant condition limiting the migration or continuance of the fauna. Following Dall in the discussion of Tertiary faunas, Arnold gave a detailed analysis of the Tertiary of the Pacific coast, and exhibited maps showing the geographic conditions at various stages from Eocene to Pliocene.

Closing the consideration of the historic succession, Knowlton discussed Mesozoic and Tertiary floras, Salisbury brought out those phases of physical geography of the Pleistocene which had special relations to conditions bearing on correlation, and MacDougal presented a consideration of the origination of self-creating matter and the influence of aridity upon its evolutionary development.

The symposium was closed by Chamberlin, who discussed diastrophism as the ultimate basis of correlation. The speaker emphasized the view that diastrophism is the basal phenomenon according to which other phenomena that afford criteria for correlation are modified and developed. Taking a broad view of the whole subject, he held that the periodicity of diastrophic movements affords the criteria for determining the major divisions, but he recognized also that all the related lines of evidence are required to work out the minutiae of the problems of geologic correlation.

In connection with the discussions paleogeographic maps of North America at fifteen different periods were exhibited. They represented studies by Willis in association with a number of colleagues in regard to the geologic provinces of North America.

The arrangements for the symposium on correlation included one unusual feature, inasmuch as a definite time schedule was prepared and published in the program, and this schedule was strictly adhered to during three days' proceedings. In general, about three quarters of an

hour was allowed for the presentation and discussion of each topic; the principal speaker took thirty minutes or less; the remainder of the time was given to discussion of the subject as presented by him. The following speaker was not allowed to begin until the hour stated on the program had arrived. This plan appeared to work to the satisfaction of the audience; the speakers confined themselves practically to the time allotted, and their convenience and that of all who had an interest in the subject was satisfactorily served.

The papers contributed to the symposium will appear in the *Journal of Geology* of Chicago University, in chronological order.

Monday morning at 11 A.M. in a subsection, with G. K. Gilbert as chairman, the following papers were read:

Some New or Little-known Geological Terms and their Application in Stratigraphic Writing:
A. W. GRABAU.

The following terms were discussed and defined:

1. *Disconformity*, proposed by Grabau in 1905 to cover unconformable relation of strata where no discordance of dip exists, the term *unconformity* being restricted to cases with perceptible discordance of dip.

2. *Rudaceous* and *rudyte*, *arenaceous* and *arenyte*, *lutaceous* and *lutyte*, proposed by Grabau in 1904 for pebbly, sand and mud rocks, respectively, irrespective of their composition; classification of clastic rocks by texture being advocated. According to composition we may have: *siliolrudytes*, *silioarenytes*, *silioilutytes*; *caloirudytes*, *caloarenytes*, *caloilutytes*; *argillutytes*, etc.

3. *Chronofauna* and *chronoflora* and *locofauna* and *locoflora* (new), the first two for fauna and flora of a given time period, the other two for the fauna and flora of a locality.

4. *Epiplankton* (new) for organisms attached to floating objects and not primarily planktonic. There have been included under this term *pseudoplankton*, which it is proposed to restrict to dead organic and to inorganic planktonic matter.

5. *Epicontinental sea* to be restricted to the shallow seas lying within the continents and constituting with the *mediterraneans* the *intracontinental seas*. The term *littoral* to be applied as in zoology to the district extending from high water to limit of sun-illuminated bottom (edge of continental shelf in the oceans) and characteristic of oceans, intracontinental seas and lakes. The term *epicontinental sea* is not to be applied to the littoral district of the oceans as thus defined.

6. *Migration* to be active—in search of food, escape from enemies, etc.; *dispersal* to be passive—by currents, water or air, etc., or by carriage by other organisms, etc.

This paper was discussed by G. K. Gilbert.

Some Preglacial Valleys in Eastern New York and Their Relation to Existing Drainage: JOHN H. COOK.

The valley of the Mohawk from Schenectady to the Hudson River is of post-glacial origin, as shown by the fact that between Niakayuna and Fort's Ferry it crosses a filled channel, trending north-northeast towards Round Lake and south towards Albany (at which city this channel probably opens into the Hudson valley).

For two miles above Schenectady borings along the Mohawk developed no rock at a depth considerably below the rock bottom of the river at the entrance to the upper gorge near Rexford Flats.

The channel of the preglacial Mohawk lies beneath the sediments of glacial Lake Albany, but may be traced approximately. It parallels, roughly, the Helderberg escarpment and probably reaches the Hudson just north of Coeyman, where there is a break in the rock wall elsewhere almost continuously exposed for several miles north and south of that point.

Drift and sands and clays deposited during the retreat of the ice sheet had filled these channels and spread widely over the divides when the re-excavation of the Hudson valley and the draining of Lake Albany were accomplished. The waters of Lake Iroquois still found outlet through the Mohawk valley as far as Schenectady, but, as a point near Rexford Flats lay at an elevation below the level of the deposits immediately south and west, the stream there poured over the low divide, crossed the filled channel mentioned above and took the course it now pursues to the Hudson.

This paper was discussed by G. K. Gilbert and F. P. Gulliver.

Monday afternoon, following the vice-presidential address of J. P. Iddings on "The Study of Igneous Rocks," the reading of papers was continued.

The Metamorphism of Glacial Deposits: FRANK CARNEY.

Till and tillite are two extremes in the structure of glacial deposits.

So far as we yet know, the periods of glaciation are spaced by long lapses of time; therefore we have only disconnected data in the metamorphic cycle of glacial sediments.

Evidence is adduced tending to show: (1) That some chemical activities are accentuated by the saturated condition of sediments beneath an ice-sheet. Carbonation and hydration would be enhanced, and even oxidation may occur. (2) That the great pressure to which unconsolidated materials of an earlier drift sheet are subjected by a later invasion of ice is an important agent of alteration. This pressure based on a conservative estimate of the thickness of the ice amounts to over nine thousand pounds per square inch. Not only are these materials made compact, but they are faulted and jointed. Furthermore, this density increased capillarity which has operated in more recent alterations. In addition to the pressure of a superincumbent ice-mass, it is probable that hydration has increased the pressure-effects.

This paper was discussed by George D. Hubbard.

A New Occurrence of Carnotite: EDGAR T. WENNER.

A supposed occurrence of autunite at Mauch Chunk, Pa., has been investigated, and the material found to be similar in character to the Colorado carnotite. It occurs in layers of conglomerates at the top of the Mauch Chunk red shale on the west side of the Lehigh River, one mile north of the town, having been extracted from insular lenses of black shale and graywacke and deposited in fissures and porous beds by circulating surface waters. The dark color of these lenses is due, not to carbon, but to the presence of comparatively fresh hornblende, biotite, etc., resulting from the disintegration of the metamorphic rocks of the highlands to the south and east during the arid climate prevailing in late Mississippian times, and much of the vanadium and uranium originally distributed through these rocks are concentrated in them. As the western deposits of carnotite occur in similar positions, namely, in arenaceous formations overlying red shales, it is suggested that they may have had a similar origin.

The Phenomena of Eolian Sand Drift: E. E. FREE.

Wind-drifted sand moves by "saltation" or in a series of leaps in a manner quite analogous to the recently described by McGee for the suspended matter of streams. The forms shown by collections of such sand are of two main types: (1) the large heaps or dunes, (2) the minor surface figures, of which ripples form the best example. Previous discussions of dune formation are satisfactory except that far too little importance has been assigned to the eddy behind the

dune. Many anomalous forms can be explained as due to it. Ripple formation is probably connected with the production in the moving air of eddy systems analogous to the Helmholtz vortex-surface.

This paper was discussed by O. H. Richardson, George D. Hubbard, J. H. Cook, G. K. Gilbert and F. P. Gulliver.

The following papers were read by title.

The Mills Moraine, with Some General Remarks on the Glaciation of the Longs Peak Region of Colorado: EDWARD ORTON, JR.

The Longs Peak group is a mountain mass with several summits, lying in front or east of the continental divide and connected with it by one narrow and much-dissected ridge or spur. The district is very wild and rough and existing maps are of the most elementary sort and furnish no accurate details. The highest peak is 14,271 feet high and the mass as a whole, towering 1,000 or 1,500 feet above the general summit level of the main range of the Rockies, is easily the dominating point of northern Colorado.

Separating the main range and the Longs Peak group are deep gorges occupied by the head waters of the Big Thompson and the St. Vrain rivers. The heads of these gorges, winding around behind Longs Peak, cut deeply into the connecting ridge, and have nearly isolated the group from the main range, of which it was once an integral part.

The high valleys and cirques lying between the main range and the western slopes of the Longs Peak mass, offered an excellent gathering ground for snows, owing to the great elevation of the peak and the position of the gorges with reference to the prevailing winds and storms. Great glaciers developed there, and made their way out north and south, curling around to the eastward past the base of the great peak on either side, and building magnificent moraines along their flanks and termini. The nature, location and general topographic features of these moraines is discussed, and some evidences of periodicity in their development is noted.

On the east side of the Longs Peak group, located in a small cirque between the three highest summits, a small but very active glacier has been at work, and has built up a very beautiful moraine system, entirely independent of the general glaciation of the district. On account of this isolation, these moraines offer a very good opportunity for a study of the periodicity of the glacial phenomena of the mountain areas of the west.

A topographic map drawn from original surveys of the gorge of this, the Mills glacier, and the moraines which it built, has been prepared.

*The Red Beds of the Wichita-Brazos Region of North Texas.** C. H. GORDON.

The region to which this paper relates is of special interest as having furnished the data for the discussions on the Texas Permian which have appeared in various publications in recent years. In the study of the underground water conditions of the region under the auspices of the U. S. Geological Survey, it was observed that the red sandy shales and red sandstones so conspicuous in the Wichita valley region were replaced southward in large part by blue shales, light-colored sandstones and limestones. In some places the transition from a sandstone into a limestone was plainly seen. Formations to which the names Wichita and Clear Fork have been given, when traced along their strike toward the southwest, are found to grade into those included under the terms Cisco and Albany. The former have been regarded as Permian, while the latter have usually been assigned to the Pennsylvanian. Some authors, however, have suggested that the Albany should be considered Permo-Carboniferous. An abundant marine fauna characterizes the beds toward the south. In the Red Bed region marine forms are few, appearing only in the few beds of limestone that persist. Along with them in this region appear vertebrate remains upon which the references to the Permian have been based. It is the conclusion of the author that the Red Beds of this region are the near-shore representatives of the Albany and the decision as to their age will rest upon that of the latter.

The Invertebrate Faunas and Correlation of Some So-called Permian Rocks of the Mississippi Valley, with Remarks on Their Stratigraphy. J. W. BEEDE.

Discussion of the stratigraphy, fossils and correlation of the higher Paleozoic rocks of Kansas and Nebraska and their correlation with rocks of the United States and Eurasia. Remarks on stratigraphy and paleogeographic conditions under which faunas lived, and a few fundamentals of paleontologic correlation.

Differential Effects of Eolian Erosion upon Rock-belts of Varying Induration. CHARLES R. KEYES.

The desert regions of our country may be regarded as comprising those tracts where the annual amount of rainfall is less than ten inches.

* Published by permission of the director of the United States Geological Survey.

More than nine tenths of whatever rainfall there is sinks at once into the dry and thirsty soil and does not appear as stream-water at all. The only perennial rivers are those whose headwaters are extralimital and whose courses merely traverse the arid region on the way to the sea. With so small and unimportant precipitation characteristic of the arid country, the high evaporation, often several times greater than the amount of annual rainfall, and the loose dry soils, wind-scour becomes a far more potent erosive agency than is usually fancied.

The sequence of geologic terranes and their lithologic characters in the desert region, and particularly in the northern part of the Mexican tableland where the isle-like aspects of the mountain ranges dotting a vast sea of earth is so characteristic of what the Germans in the South African deserts have so aptly termed the "Inselberglandschaft," are such as to permit eolian influences to fashion their finest subjects of delicate sculpture. Ten thousand feet of hard limestones are succeeded by an even greater thickness of soft shales and friable sandstones. On account of frequent and profound faulting which, in early Tertiary times, the region had undergone and the subsequent planing off of the country to the condition of a peneplain, there has been imparted to the areal distribution of the geologic formations a remarkable alternation of belts of resistant and weak rocks.

General desert-leveling and lowering of an elevated country by deflation is comparable in the nature of its larger relief effects to that of general corrasion in a humid climate. It is in the arid region that the eolian influences as erosional processes find their maximum activities. In the dry lands the weaker rock-masses are rapidly removed; while the harder belts long resist deflative attack. Under conditions of aridity, the differential effects of wind-scour, or deflation, upon rock-belts of contrasted induration are very different from what they are in a normal moist climate. The inequalities of surface relief are in consequence very much more intensified than when stream-action is the chief eroding agent. In general, it may be estimated that in the case of hard rock-masses in an arid land deflative erosion is probably less than one tenth as efficient as in a normal wet country water-action would be; while in the case of weak rocks it is more than ten times greater. This is, no doubt, one of the principal reasons why to most observers in the desert regions such manifest evidences of enormous ero-

sion are so impressive on every hand, while the recognized absence of an abundance of running waters makes it appear that the progress of erosion must be extremely slow.

In southwestern United States, where the lofty and numerous desert ranges have been regarded as having developed out of an old peneplain, a remnantal portion of which seems to be represented in the great Mesa de Maya, where through faulting and folding there has been produced a rapid succession of resistant and weak rock-belts, where deflative phenomena are thought to be typically expressed, and where there are several large rivers flowing from the humid zones of the higher Rockies in deep canyons through to the sea, there appears to be all of the data at hand by which to measure not only the relative rapidity of deflation upon contiguous areas of hard and soft rocks, but also to gauge the comparative effects between erosion by direct deflation and erosion by corrasion unaided by extended chemical decomposition of the rocks at the surface.

Locus of Maximum Lateral Deflation in Desert Ranges: CHARLES R. KEYES.

Deflative erosion in an arid land is preeminently plains-forming. Its general effects are best likened to the work of the sea along an exposed coast where there is carved out of the shore a marine platform. In a smaller way, as a detritus-laden stream impinges against its banks, forming high bluffs or cliffs, so in the dry regions the swiftly moving air-current heavily charged near the ground with sands and dusts tends to wear away fastest the least sheltered portions of the desert hills and mountains.

The air-currents of the desert are both strong and constant. Their transportative powers have never been measured quantitatively. When transportation is active the "sandstorm" results. The personal discomfort to the traveler in a sandstorm is so very great that he is usually oblivious to all else. The volume of soil flowing along the surface of the ground during one of these storms must be prodigious. Compared with the amount of sediments carried along by some large river, as the Mississippi in time of flood, it is estimated that in the lower twenty feet of the deflation-stream there are equal amounts of rock-waste moving in like cross-sections of the great river and of the air-stream of the desert. The air-stream moves forty miles an hour instead of four, as in the case of the water-stream; and in place of being only a mile wide the path of the sandstorm is several hundreds of miles in width. The

lower six inches of the air-stream is almost wholly moving sand and fine gravel. The finer dust sears upwards thousands of feet, darkening the light of the sun as by a heavy thunder-cloud.

Over surfaces of drifted sands and of weak rocks the erosion is mainly accomplished by a trituration of the particles of the heavily sand-laden bottom stratum of moving air. Whenever bare or hard rock-masses are encountered there is vigorous sand-blast action. Thus, hypsometrically, among the desert ranges which are all composed of very hard rocks usually devoid of a soil-mantle, the notably exposed zone is at the very base of the mountains, or immediately above the surface level of the surrounding plains. This is probably the chief reason why there are no foothills flanking the mountain ranges of the desert, why mountain and plain so sharply meet, and why the bases of the desert ranges are often so abrupt and straight as to suggest at once the presence of fault-scarps as an explanation of the steep faces to the mountains.

When we institute search for direct evidences of fault-lines which are supposed to give rise to the escarpments, we usually look in vain. Although the mountain may be a faulted block the movement, however profound, is commonly discovered to be of ancient date. Its fault-plane is found to be far out in the plain, often at distances of four or five miles. The intervening space has a smooth and gently sloping rock-floor and has every appearance of a marine plain of denudation from which the sea has but recently retired. McGee¹ notes many such plains with extensive rock-floors fashioned from the hardest rocks, among the desert ranges of Sonora in Mexico. Others are described more in detail in the New Mexican region.² They are now widely known throughout the arid lands of the west. Thus, in the general leveling and lowering of the desert region anciently faulted and planed off so as to present alternating belts of resistant and weak rocks the areas of the latter are worn chiefly downward by the wind-action, but the hard mountain belts which have emerged from the softer areas are attacked laterally; and the zone of maximum isolation is at and just above the general plains-level.

A New Trachodon from the Laramie Beds of Converse County, Wyo.: CHARLES H. STEENBERG.

A complete skeleton, except hind feet, one tibia and fibula and tail vertebra. It lies on its back

²*Ibid.*, XIX., p. 78, 1908.

and the soft cross-bedded sand contains the impression of the skin that entirely envelops the bones, which are nearly all in normal position. The contents of the stomach are also preserved. It will be mounted as in death by the American Museum of Natural History.

Isobases of Post-Algonquin Elevation Across Lakes Michigan and Huron: J. W. GOLDTHWAIT.

The results of precise measurements of altitude of the Algonquin beach, during the last four years, are here summarized.

With data collected last summer for the Canadian Geological Survey, isobases of the deformed water-plane are constructed over the region east of Lake Huron and Georgian Bay in Ontario. It is found that at the south end of Lake Huron the Algonquin beach is horizontal, and twenty-five feet above the present lake; that forty or fifty miles north of Sarnia the beach begins to rise towards the north-northeast, at a rate which increases slowly to three feet per mile over Lake Simcoe, and then very rapidly north of Orillia to five feet per mile near the pre-Cambrian border. Beyond that, to North Bay, the warping seems to have been much more irregular.

The attitude of the deformed Algonquin plane, south of the pre-Cambrian boundary in Ontario, is compared with that over the north half of Lake Michigan, three hundred miles away. Isobases drawn across Lakes Michigan and Huron emphasize the close correspondence in the details of post-Algonquin uplifts in these two regions.

Conclusions are drawn as to: (1) The regularity of the uplifts over the Great Lake region, south of the pre-Cambrian border; (2) the southern limit of the uplifts; (3) the original altitude of Lake Algonquin above sea level and (4) the cause of the uplifts.

Sand and Gravel Resources of Nebraska: G. E. CONDER.

This paper is now in press. It consists of 210 pages of text and 82 figures in Part 3 of Vol. 3, Nebraska Geological Survey.

The Glacial Character of the Yosemite Valley: F. E. MATTHEW.

The Yosemite is a stream-worn canyon modified by ice erosion. That it is primarily a product of stream cutting no one familiar with its relations to the rest of the Merced River canyon, and with the position which the latter occupies in the series of great transverse valleys of the Sierra Nevada, will question. That it has been invaded by glaciers, on the other hand, and has to some extent been remodeled by them, is amply attested

by the threefold record of glacial moraines, striae and glacial sculpture about the valley. The glacial character of the Yosemite is however by no means equally prominent throughout: most accentuated at the upper end, it rapidly fades downvalleyward and ultimately vanishes at the lower end. This variation is explained by the circumstance that the valley lay close to the periphery of the glacial mass of the Sierra. In earlier glacial times the ice advanced considerably beyond the foot of the valley, but the later glaciations appear to have been more moderate, the ice front seldom reaching down to the "gateway." The lower portion of the valley bears therefore no fresh signs of glaciation, and since the older icework has been considerably obliterated by subaerial erosion, its glacial character can now scarcely be detected except by the trained eye. The upper half of the valley, Tenaya Canyon and the Little Yosemite, on the other hand, having suffered more frequent, more intense and also more recent glaciation, have been extensively remodeled and present today a glacial aspect of the most pronounced and clear cut type.

The disparity between the lower and upper portions of the Yosemite is further heightened by the presence in the latter of a variety of prominent sculptural features. The ice had to deal here with rock-masses of singularly variegated structure, ranging all the way from the schistose to the massive. Since ice accomplishes most of its work by plucking, its effectiveness as a sculpturing agent is largely determined by the fissility of the materials it attacks. Its action in the Yosemite was therefore necessarily a selective one, guided and controlled locally by the direction, attitude and distribution of the joints. Thus it was particularly to achieve large results where the intensity of the fissuring favored plucking, as in the region about the Cathedral Spires, while it found itself almost powerless against such huge masses of unjointed rock as Mt. Broderick, El Capitan or the Cathedral Rocks. Again, the remarkable wall-like smoothness as well as the orientation of the cliffs over which the waterfalls plunge reflects the strong directive influence of the rock structure.

LIST OF PAPERS READ BEFORE THE GEOLOGICAL SOCIETY OF AMERICA

Abstracts of these papers have been sent to SCIENCE by the secretary of the Geological Society of America.

President Calvin's address, "The Latest Phase of the Pleistocene Problem in Iowa."

Physical and Structural

Some Distinctions between Marine and Terrestrial Conglomerates: JOSEPH BARRELL.

The Chemistry of the Pre-Cambrian Rivers: REGINALD A. DALY.

The Primary Origin of the Foliated Structure of the Laurentian Gneisses: FRANK D. ADAMS and ALFRED E. BARLOW.

Relations of Present Profiles and Geologic Structure in the Desert Ranges: CHARLES R. KEYES.
Deflation and the Relative Efficiencies of Erosive Processes under Conditions of Aridity: CHARLES R. KEYES.

Unconformity Separating the Coal-bearing Rocks in the Raton Field, New Mexico: WILLIS THOMAS LEE.

Evidence that the Appalachian and Central Coal Fields were once Connected across Central Kentucky: ARTHUR M. MILLER.

The Bearing of the Tertiary Mountain Belt upon the Origin of the Earth's Plan: FRANK BURSLEY TAYLOR.

On Faults: HARRY FIELDING REID.

Mass Movements in Tectonic Earthquakes: HARRY FIELDING REID.

The Alaskan Earthquake of 1899: LAWRENCE MARTIN.

A Recent Landslide in a Shale Bank near Cleveland accompanied by Buckling: FRANK R. VAN HORN.

The Volcano Kilauea: C. H. HITCHCOCK.

Mt. Pelé of Martinique and the Soufrière of St. Vincent in May and June, 1902: EDMUND OTIS HOVEY.

Glacial

Multiple Glaciation in New York: H. L. FAIRCHILD.

Glacial Waters West and South of the Adirondacks: H. L. FAIRCHILD.

Correlation of the Hudson and the Ontarian Glacier Lobes: H. L. FAIRCHILD.

Pleistocene Features in Northern New York: H. L. FAIRCHILD.

Pleistocene Geology of the Southwestern Slope of the Adirondacks: W. J. MILLER.

Weathering and Erosion as Time Measures: FRANK LEVERETT.

The Glacial Phenomena of Southeastern Wisconsin: WM. C. ALDEN.

Concerning Certain Criteria for Discrimination of the Age of Glacial Drift Sheets as Modified by Topographic Situation and Drainage Relations: WM. C. ALDEN.

Lake Ojibwa, the Last of the Great Glacial Lakes: A. P. COLEMAN.

Glacial Erosion on Kelley's Island, Ohio: FRANK CARNEY.

Interglacial Epochs: ALBRECHT PENCK.

Stratigraphic

The Chalk Formations of Northeast Texas: C. H. GORDON.

Geologic History of the Ouachita Region: E. O. ULRICH.

Some Results of an Investigation of the Coastal Plain Formations of the Area between Massachusetts and North Carolina: WM. BULLOCK CLARK.

The Geologic Relations of the Cretaceous Floras of Virginia and North Carolina: EDWARD W. BERRY.

Occurrence of the Magothy Formation on the Atlantic Islands: ARTHUR BARNEVELD BIBBINS.

Erosion Intervals in the Tertiary of North Carolina and Virginia and Their Bearing upon the Distribution of the Formations: BENJAMIN L. MILLER.

The Character and Structural Relations of the Limestones of the Piedmont in Maryland and Virginia: EDWARD B. MATHEWS and J. S. GRANT.

Recurrence of the Tropicidoleptus Fauna and the Geographic Range of Certain Species in the Chemung of Maryland: CHARLES K. SWARTZ.

The Geological Distribution of the Mesozoic and Cenozoic Echinodermata of the United States: WM. BULLOCK CLARK and M. W. TWITCHELL.

On the Age of the Gaspé Sandstone: HENRY S. WILLIAMS.

Revision of the Paleozoic Systems in North America: E. O. ULRICH.

The Aftonian Sands and Gravels in Western Iowa: B. SHIMEK.

An Aftonian Mammalian Fauna: S. CALVIN.

The Brachiopod of the Richmond Group: A. F. FOERSTE.

Areal

The Trap Sheets of the Lake Nipigon Basin: ALFRED W. G. WILSON.

Reconnaissance in Arizona and Western New Mexico along the Santa Fé Railroad: N. H. DARTON.

Geologic Studies in the Alaska Peninsula: WALLACE W. ATWOOD.

Our Present Knowledge of the Oklahoma Red Beds: C. N. GOULD.

Paleontology

The Fauna of the Glen Park Formation: STUART WELLER.

Petrology

Some Features of the Wisconsin Middle Devonio: H. F. CLELAND.

A Classification of Crystals based upon Seven Fundamental Types of Symmetry: CHARLES K. SWARTZ.

Quartz as a Geologic Thermometer: FRED. E. WRIGHT and E. S. LARSEN.

The Use of "Ophitic" and Related Terms in Petrography: ALEXANDER N. WINCHELL.

Ice-borne Boulder Deposits in mid-Carboniferous Marine Shales: JOSEPH A. TAFF.

Chemical Composition as a Criterion in Identifying Metamorphosed Sediments: EDSON S. BASTIN.

Petrography of the South Carolina Granites (Quartz Monzonites): T. L. WATSON.

Physiographic

Tertiary Drainage Problems of Eastern North America: AMADEUS W. GRABAU.

Pre-Glacial Drainage in Central New York: H. L. FAIRCHILD.

Some Practical Results of the Ninth International Geographical Congress: H. G. BRYANT.
A Remarkable Glacial River and Its Modern Representative: F. B. TAYLOR.

The Baltimore meeting was one of great interest to geologists and geographers, not only on account of the large number of papers presented, many of which had to be read by title, but also because there were so many opportunities to meet men from different sections of the country and to discuss and compare individual fields of work, without which great advance in science can not be made. Great credit should be given to the members of the Geological Department of Johns Hopkins University for the arrangements of the details of the meeting.

F. P. GULLIVER,
 Secretary Section E

SOCIETIES AND ACADEMIES

TWENTY-FIFTH MEETING OF THE CHICAGO SECTION OF THE AMERICAN MATHEMATICAL SOCIETY

THE twenty-fifth meeting of the Chicago Section of the American Mathematical Society was held at the University of Chicago on Friday and Saturday, April 9 and 10, 1909. The attendance upon the various sessions numbered over sixty, including forty-six members of the society. On Friday evening forty members dined together in the café of the university commons, and discussed informally various topics of interest, including the plans for the meeting of the British Association for the Advancement of Science to be held in Winnipeg this summer, and the next International Congress of Mathematicians to be held in England in 1912.

Particular interest centered in the report of the committee appointed at the previous meeting, of which Professor E. J. Wilczynski was chairman, and whose purpose was to devise a plan by which it might be possible for the society to aid in securing better methods of making mathematical appointments in the colleges and universities of this country. The paper read by Professor Wilczynski at the preceding meeting was published in full in *SCIENCE* for February 26, 1909. The committee reported that they had been unable to recommend for consideration any plan for improvement by action of the society. But, nevertheless, the members of the section were greatly interested in the details of a plan proposed by Professor Wilczynski and formally requested the secretary to incorporate this in the minutes of the meeting.

Twenty-six papers were presented at the four half-day sessions of the section, all of the authors being present except Dr. Ranum and Professors Ames and Davis, whose papers were read by title.

Following are the titles of papers and the authors:

On a Class of Discontinuous Functions of Two Variables: Professor C. N. HASKINS, University of Illinois.

The Fermat Number $2^{2^m} + 1$: Mr. A. E. WESTERN, London, England; Dr. J. C. MOREHEAD, Northwestern University.

A Simplification of Lagrange's Method for the Solution of Numerical Equations: Dr. J. C. MOREHEAD.

Oscillations near Lagrange's Equilateral Triangle Points in the Problem of Three Bodies: Mr. THOMAS BUCK, University of Chicago.

On the Equivalence of Pairs of Quadratic Forms under Rational Transformations: Professor L. E. DICKSON, University of Chicago.

The Group of Classes of Quadratic Integers with Respect to a Composite Ideal as Modulus: Dr. ARTHUR RANUM, Cornell University.

On Surfaces having Isotherm-conjugate Lines of Curvature: Professor A. E. YOUNG, Miami University.

A Set of Criteria for the Summability of Divergent Series: Professor W. B. FORD, University of Michigan.

On the Determination of the Asymptotic Developments of a Given Function: Professor W. B. FORD.

A Class of Periodic Orbits of Three Finite Bodies: Mr. H. E. BUCHANAN, University of Chicago.

Automorphisms of Order Two: Professor G. A. MILLER, University of Illinois.

The Attack on the Space and Time Concepts by Einstein and Minkowski: Mr. R. P. BAKER, University of Iowa.

An Imaginary Conic: Professor E. W. DAVIS, University of Nebraska.

Groups of Rational Integral Transformations in a General Field: Dr. L. I. NEHREBE, University of Illinois.

A Theory of Invariants: Professor L. E. DICKSON.

Combinants: Professor L. E. DICKSON.

Maschke's Symbolic Method Applied to some Questions in Geometry of Hyperspace: Mr. W. H. BATES, Purdue University.

A Simpler Proof of Lie's Theorem for Ordinary Differential Equations: Professor L. D. AMES, University of Missouri.

Periodic Orbits about an Oblate Spheroid: Dr. W. D. MACMILLAN, University of Chicago.

On the Effect of Types of Correspondence on Bravais's Coefficient of Correlation: Professor H. L. RIETZ, University of Illinois.

Oscillating Satellites when the Finite Bodies Describe Elliptic Orbits: Professor F. R. MOULTON, University of Chicago.

Projective Differential Geometry of Developables: Professor E. J. WILCZYNSKI, University of Illinois.

Complete Elementary Theory of Certain Properties of Classes of Functions: Mr. ARTHUR PITCHER, University of Chicago.

Remarks on the General Theory of Point Sets: Mr. T. H. HILDEBRANDT, University of Chicago.

Biorthogonal Systems: ANNA JOHNSON PELL, University of Chicago.

On the Solution of Linear Differential Equations with Periodic Coefficients: Professor F. R. MOULTON, Dr. W. D. MACMILLAN, University of Chicago.

H. E. SLAUGHT,
Secretary of the Section

THE TORREY BOTANICAL CLUB

The meeting of March 9, 1909, was called to order at the American Museum of Natural History at 8:30 P.M., with Dr. E. B. Southwick in the chair. About fifty persons were present. After the reading and approval of the minutes of the preceding meeting, the club listened to a very interesting lecture on "Ferns," by Mr. Ralph C. Benedict. The lecture was illustrated by lantern slides made from photographs taken by the speaker.

SOME TRENDS IN HIGHER EDUCATION¹

THE student of the higher educational system can not help becoming impressed by certain very pronounced phenomena. These grow most obvious if the graphical method is used for the expression of tabulated data, and that method has therefore been relied upon here to visualize the movements under discussion.

First among the phenomena, and bearing all the others in its train, is the remarkable growth and spread of interest in higher education, and the consequent tremendous increase in the number of those pursuing advanced studies and receiving higher training.

Chart No. 1 deals with the conditions in Germany as disclosed by a study of educational statistics compiled from official sources.² It is natural for us to look to Germany for significant educational movements and well-kept statistics. An examination of Curve B of the combined

¹The charts which form the basis of this paper are part of those which have been constructed by the writer for his use in studying certain movements bearing upon the problem of educational efficiency. Effort has been made to have the data as complete and accurate as the time at his disposal for this work would permit, although it is too much to hope that no minor errors or discrepancies have been overlooked.

For data furnished, other than those available in official publications, he wishes to make especial acknowledgment to Presidents Schurman, Van Hise, Wheeler and Jordan and their respective secretaries.

²Lexis's "Public Education in the German Empire"; Ascherson's "Kalender der deutschen Universitäten" and "Minerva."

attendance at the twenty-two German universities reveals at once the most striking fact developed in the course of this investigation. It will be seen that prior to 1870 (the year of the Franco-Prussian war) this attendance was fairly uniform (the yeast of the spirit of 1848-9 can, however, be seen to have been slightly working), keeping regular pace with the population and thereby betokening a certain stable condition of the social order. Immediately after this date we find the curve taking a sharp upward bend and an increase in attendance growing much more rapidly than the population. Nor does this increase show the slightest tendency to fall off. It is even more marked if we plot the combined attendance at all the German universities, polytechnic and professional colleges above gymnasial rank as in Curve A.⁷

At the beginning of the period of rapid development (1870) we find one student for every two thousand inhabitants, while in 1907 we find one student for every thousand inhabitants. This denotes twice as wide-spread a participation in the benefits of higher education—and, involving, as this must, higher personal efficiency, needs and aspirations, it is not too much to claim that we are well on the way toward an entirely new social order; that we are in the midst of an intellectual renaissance of profoundest import, of a movement which is one of the most significant in the history of the development and progress of the race.

Were Germany alone in this movement so broad a statement would be unjustifiable—but she does not stand alone, she is simply preceding the other nations.

Chart No. 2 deals with the statistics for the United States and is based upon data

⁷The disturbed political conditions of 1887-8 show in the form of an offset in both curves; more marked in B.

compiled from annual Reports of the Commissioner of Education. Curve B gives the combined attendance at all the colleges, universities, scientific, technical and professional schools, omitting preparatory departments. Up to the year 1885 we see a condition of practical stability, but beginning with that year the curve takes an upward bend and continues with no sign of falling off. We see repeated the same story told by the German curves but beginning fifteen years later. In 1885 we find one student for every seven hundred inhabitants, twenty years later, in 1905, one for every four hundred—or, if we include the Normal School attendance as given by Curve A, one for every three hundred inhabitants.

Even though the United States shows the same phenomenon, our broad statement might have to be qualified. But the following table (I.) shows that the movement is not confined to these two countries. Here we see that Russia is the only western country of prominence which has not passed Germany's figure of the year 1870, namely, one student for two thousand inhabitants. Perhaps the most striking fact displayed by this table is the way Great Britain has lagged in this vast movement of the democratization of the advantages of higher education—and, scarcely less significant, the strong leading position of the United States.

To analyze the forces underlying this great wave of emancipation, fascinating as the study may be, is a task lying beyond our present powers. It remains a problem for the future historian. We must content ourselves with noting the phenomenon and passing on to some of its effects. It is also to be noted in passing that going side by side with the great increase in numbers there has been a vast improvement in the standards of the edu-

TABLE I

Country	Population ^a	Number of Students in Higher Educational Institutions	Population per Student
United States	84,000,000	210,833 ^a	400
Switzerland	3,500,000	279,270 (Inc. Normal Sch.)	[300]
Germany	61,000,000	6,500 ^b	530
		61,287 Matriculates ^c	1,000

^c Original data not segregated.

^a Universities only. Figures taken from SCIENCE, September 25, 1908, for 1907.

^b Includes universities, technical and professional schools above gymnasial rank, 1905-6.

It is of interest to compare this vast and increasing throng of students to a powerful stream which, refusing longer to be confined within narrow, artificial banks, has burst through and found its own natural channels. What these have been can be seen from the foregoing table (II.), comparing the German student attendance in the various channels of work for the years 1869 and 1905.

The following table (III.), comparing American and German attendance, also throws light upon this phase of our subject.

is more nearly commensurate. Another item not indicated here is the much larger proportion of women students in the United States. However, this broad subject of comparison can only be touched upon and left with the statement that American standards are rapidly improving, more rapidly than they are aware who have not been giving attention to the subject.

In the light of these charts and figures is it too much to claim that they betoken a rapid breaking down of old forms of caste, class and privilege—a great social

TABLE III

Comparison of Attendance of Various Courses in Germany and the United States 1905-6

	United States	Germany	Ratio $\frac{U. S.}{G.}$
Population	83,935,000	60,314,000	1.39

Data from Ascherson, Lexis, Minerva and Report of U. S. Commissioner of Education, 1906.

In making this comparison too definite conclusions must not be drawn, ~~as~~ the writer is well aware of the differences in standards and curricula. Thus it is probable that quite one half of our collegiate students are doing work of German gymnasial grade. In the technical and professional fields it is possible that the work

upheaval signaling the imminence of a new social order? Can no connection be traced between this increasing stream of trained young men and women taking up their duties of citizenship, and the great wave of awakening to a higher sense of social obligation and civic righteousness now rising in our country?

⁹ Not segregated in German data. In United States, 900 Arch., 9,300 C. E. and 2,700 Gen'l Eng.

¹⁰ Computed on basis of returns for 86.5 per cent. of total. See Report U. S. Commissioner of Education, 1906, p. 446.

¹¹ In 1902 there were 1,095 Arch. and 2,852 C. E. On a proportionate division this gives in 1905-6, 2,220 Arch. and 3,223 C. E.

It is folly to dream of checking this mighty stream or of turning it back into the banks of a narrow scholasticism. Our problem is to provide adequate and suitable channels for it. Conditions are rapidly changing and we, as educators, must face the facts as they are.

The profound demand of this army of nearly three hundred thousand students in our country to-day is for an education which will enable them to live most worthily and effectively the life of to-day and to-morrow. The demand, which will not be denied, is for breadth of culture coupled with an effective bearing upon the needs and problems of life—a culture whose key-note shall be efficiency in action and service.

Charts 3-7 show the trend of growth of student body. It is interesting to remark that each one of these institutions which was established before 1885 shows the same general trend of increase, as is shown by Curve B of Chart 2, the curve of combined attendance at all higher American institutions of learning. Slight irregularities, due to local conditions, such as change of entrance requirements, etc., are, to be sure, to be observed. In common

Passing from the general aspect of our problem to certain effects brought in its train, it is significant to note the results wrought upon the individual institutions. For the purposes of this investigation five typical American universities have been selected. Geographically they form a chain across our country and in type they represent institutions resting upon private foundations, public foundations and combined public and private foundations. They are Harvard, Cornell, Wisconsin, California and Stanford.

with Curve B they show the effect of the hard times following 1873 and 1893 in the form of a decided offset or sag. A similar effect may be expected in the years following 1907. It will be noted that the effect is a delayed rather than immediate one. Each chart shows a practically uniform attendance until about 1885 and then a sharp upward bend maintained with essential uniformity. Is it not strange that institutions differing widely in their nature and separated by thousands of miles geographically should experience simul-

taneously this thrill of rebirth? Who shall maintain that the growth of any single institution, beginning at this time, was due to the direct action or influence of some particular individual or administration? No, this simultaneous action indicates a much more profound cause than this—an institution not to have been affected by this broad, fundamental movement must have definitely turned its back upon the demand of the times and refused to open its gates to an awakening people.

effect on the efficiency of the institution; and second, with respect to the possibilities of university teaching as a profession. In other words, first with respect to the *institution*, and, second, with respect to the *staff*.

1. It will be seen that the proportion of full professors in each staff has been a continuously and rapidly *decreasing* one, that the proportion of associate and assistant professors has remained about constant and that the proportion of instruct-

Aside from its effect upon the curricula of the institutions, a subject worthy of careful study, this rapid growth has wrought profound changes upon the nature and composition of the teaching staffs.

Charts 8 to 12 show the composition of the staffs year by year. These charts, like those of attendance, all show identically the same trends. They should be studied with reference to two items: First, the

ors and assistants is most alarmingly *increasing*. The cause of these trends at all of our universities is a triple one; the rapid increase in the number of students for whom instruction is to be provided, the failure of the incomes of the institutions to keep proportionate step and a deplorable rivalry in bigness and externalism leading to unwise and unnecessary expenditures for buildings and equipment. It certainly means one thing as regards

efficiency—a greater and greater share of the instruction falls upon the shoulders of the body of less experienced men and the student has a decreasing chance of working with men who have attained eminence in his line. Each recent alumnus can test the truth of this by asking himself how large a share of his work brought him into actual close and beneficial contact with the full professors in his course. Believing that the influence of personality is one of the most vital elements in training, we can but deplore the trends which separate more and more widely the student from intimate contact with men who have won recognition for success in his field of study.

Another item vitally affecting the efficiency of instruction is that this large number of instructors and assistants (from fifty per cent. to sixty-five per cent. of the staff) consists of men on temporary appointments, so that it is no unusual thing for one half of them to be entirely new appointees at the beginning of each year. The cause for this we will take up later. At present we will content ourselves by asking what can be the sole effect on the efficiency of a staff which annually loses a large proportion of somewhat trained and experienced men, whose places must be filled by beginners who must familiarize themselves with their new duties and be trained up to adequacy?

2. As regards the effect of these trends on the opportunities offered by university teaching as a profession, it need only be said that a man in the lower grades has just one third the chance of winning a place in a twenty per cent. group that he had of winning one in a sixty per cent. group. A study of the increasing average age in the ranks of associate and assistant professors at our universities bears this out.

Can it be expected that young men of

spirit will enter a profession which offers such decreasing chances of winning promotion, however well deserved, coupled with inadequate salary from the very start? What will be the effect on the teaching profession of a continuation of the trends shown by Charts 8 to 12? Interesting and valuable as is the recent Bulletin No. 2 of the Carnegie Foundation dealing with the "Financial Status of the Professor in America and Germany," it is of limited significance in making clear the actual conditions—for the full professors form but a small and rapidly diminishing proportion of our entire teaching staffs—a fact which seems to have escaped recognition.

Charts 13-17 show, that while in 1885 (at the beginning of the great upward wave of attendance) there was one full professor to from fifteen to thirty students, we now find forty to eighty students per full professor. In view of these charts of composition of staff, the writer maintains that it is the instructorship and not the professorship which is the key to the situation as regards efficiency. We will return to this point after taking up the next phase of our topic.

Next, approaching a vital aspect of efficient staff and service, we touch the question of trend of salaries.

It is to be feared that the world at large fails to appreciate our fine distinctions of adjunct professors, associate professors, full professors, senior professors, deans, and directors. To the man in the street we are all "professor," weary as we may grow of the title, and he looks to us to live up to our position. If we wish to study the actual compensation to which a man in any field may look forward, it is quite significant to know the average compensation of those who may be considered as journeymen. Leaving out all under the rank of instructor as apprentices, Charts

18-21 show the trend of average compensation of the average member of the staff at four of the institutions under consideration. The writer's pleas for the corresponding data for Harvard College were unfortunately unheeded.

The vitally significant thing about these charts is the downward trend of the curves for the past twenty years—a period of great increase in the cost of living. Coupling the increased cost of living, the improvement in the general standard of

paid ministry—in which there has not been an increase in the average rate of compensation somewhat commensurate with the increasing cost of living. Here we see no increase in the average compensation of the profession, but an actual falling off. It may be argued that this is but a natural and legitimate consequence of recruiting so heavily the lower branches of the staff in order to keep up the proportion of teachers to students. This argument falls to the ground, however,

living (a pressure which society exerts upon every man), and the decrease in actual compensation, it is not too much to say that in purchasing power the average teacher of 1908 is but sixty to seventy per cent. as well off as was his colleague of twenty years ago. It is believed that the profession of college teaching is the only field of work in the United States—not even excepting the correspondingly poorly

when we consider the increased requirements of candidates for entrance into the teaching profession over what they were twenty years ago. "The fact is that the university is at the present time able to secure for instructors as well-trained men as those who formerly received appointments as professors in the best American universities"—wrote President Schurman in one of his annual reports some

years ago. "The great and noteworthy expansion of the university, which has been brought about by the labors of the university teachers, has also been brought about at their expense," writes President Butler in one of his annual reports. Strikingly corroborative testimony is borne by a table of age of staff of Harvard College¹² in which it is seen that there was not a single member of the

reasonable pecuniary return for their services.

Charts 22-26 are valuable as segregating the data and showing the movement of salaries in each rank separately. In these, as in the average compensation charts, the downward trend from 1885 to 1905 is noticeable. Beginning with 1905, however, when this matter of salaries came to a sort of focus, there has been

permanent staff under *twenty-eight* years of age.

In spite of the annual influx of new men, it is the writer's belief, based upon study of the matter, that the average age of the *instructors* at the five institutions under consideration is just about *thirty* years. This is an age at which equally trained and gifted men in other business and professional fields of activity have obtained a firm foothold and receive some

¹² President Elliot's report, 1904-5, p. 14.

an upward trend of the salary curves at a number of institutions. Incomplete as the Harvard chart is, it is included here to show the effect of the teachers' endowment fund.

The most shocking thing revealed by a study of these charts is the status of the instructor. We have just seen what the age and training of these men is, and the large proportion they form of the entire staff; we now see that their average compensation ranges about a thousand dollars

a year in these leading institutions. The most serious danger which threatens the continued and developing efficiency of our universities lies in the unattractive and utterly inadequate salaries paid the instructors. Is it not well to make the portals through which all must enter the collegiate teaching profession reasonably attractive to men of character, spirit and ability? The writer is well aware of the satisfactions and rewards of the teacher's

part of the burden of the instruction falls, and within the limitations of their ranks must develop those who are to recruit the higher positions. Nine hundred or a thousand dollars a year for doctors of philosophy! Why should our universities place so very low an estimate upon the value of their own product? As if to discredit the rank still more, the rules of the Carnegie Foundation refuse to recognize the years spent in it as a teacher toward

life other than financial, but should not these men for the sake of the efficiency of the institutions receive salaries somewhat commensurate with the long and expensive preparation for their life work, and *adequate to insure the possibility of their intellectual development rather than retrogression?*

Is it to be expected, otherwise, that the field of university teaching will appeal to men of suitable quality? It has been seen that it is upon these men that the greater

the necessary twenty-five years of service entitling one to a retiring allowance. The writer has known of able men, loyal to their institutions, who have spent fifteen years and more in this rank before receiving deserved promotion. Furthermore, most institutions rob themselves of the younger men's natural desire to pursue advanced study and to grow, by loading them down with a heavy burden of entirely elementary work—and refusing to count years of service as instructor toward

a sabbatical leave. Surely these are short-sighted policies. Let us trust they will soon be abandoned. It is no wonder that after a fair trial of the profession for which they have prepared themselves many of the more spirited men leave it—albeit regretfully—for fields in which they can earn a respectable living, thus creating vacancies to be filled by inexperienced successors. This is the movement, earlier

capital lottery prizes in the professorial rank is far from reaching the root of the trouble. It does not touch the facts really disclosed by a careful diagnosis of the data. In truth, the effect of such a policy will inevitably be to make the actual situation worse for the great mass of teachers. This becomes clear from a study of charts 27-31.

And this is no small factor in the prob-

referred to, which seriously threatens efficiency.

Noting Charts 22-26, it is seen that the full professorship must be excepted from the downward trend of the past twenty years. In that rank—and that rank only—the average salary has increased. The effect of this, however, has been to widen the gap between the full professors and the rest of the staff. The remedy which has been proposed by some writers—notably President Pritchett—of bettering the general situation by offering a few

lem. It may be claimed that relative equity is of more importance than almost any other item touching compensation. Bearing in mind what has been said about age and preparation, do the conditions justify these great differences? It must be borne in mind that a university is not akin to a large factory or business organization in which the various classes of employees are separated by wide social gaps—each one moving in his own circle. On the contrary, by taste, training, ability and aspiration we belong to one compact

class—and the reciprocal demand between society and ourselves is far more a question of our age and corresponding family responsibilities than one of relative rank in our institution. As has been said, to the man on the street we are all "professor." Careful observation for a number of years leads the writer gravely to doubt the differences in value of men to institutions which these averages indicate. It is his judgment that the sifting proc-

vance of his financial obligations to keep in touch with what the leaders in his field are doing by attending their meetings and joining the associations for mutual improvement and advancement of knowledge; to indulge himself in the prompt purchase of books, periodicals and in the satisfaction of other intellectual needs. The most heart-breaking sight in our university communities is to watch the hopeless struggle in which men of brilliancy

ess which has gone on from the lower grade schools, through the high schools, colleges and universities, results in the final selection of a few men of very nearly similar gifts and training for recruits to the profession; their further growth and development are largely a matter of opportunity rather than anything else. Here, as elsewhere, "to him that hath shall be given" rules supreme. Fortunate is he who is early able to get sufficiently in ad-

and promise, gripped by economic factors beyond their control, as in a vise which prevents their growth and development, suffer final narrowing and embittering defeat. It is a tremendous waste of expensively trained material.

The scale of salaries should justly be fixed in accord with the cost of living in the community in which an institution is located. But contrary to general belief—and on this subject the writer has in his

possession interesting and valuable data—the cost of maintaining the *same standard* of living is very slightly different throughout our whole country. The difference comes in mainly as a question of the allowable or *prevailing standard*. The wife of a professor in a prairie state “land grant” college, let us say, may quite properly come to her husband’s assistance by increasing the family exchequer through keeping chickens; the wife of a professor in New York City, from equally laudable motives, and without danger of incurring unfavorable criticism, may deplete the exchequer by giving elaborate dinners toward a similar end—but were either to adopt the method of the other she would at once be made to feel the impropriety of her course. It is even conceivable that each might think she would like to try the other plan for a change. The situation grows too complex for us to follow further. *De gustibus non disputandum*—and so we will leave this question of absolute standards.

Returning, however, to the matter of relative standards, it is fair to query, is it not possible to establish a relatively equitable standard as between the various ranks? We find Harvard paying her instructors 23.7 per cent. of what her full professors average. Cornell pays 29.1 per cent.; Stanford, 29.5 per cent.; California, 33.4 per cent. and Wisconsin, 38.5 per cent. There is a difference of opinion here of 50 per cent. as to the relative value of these men. Which is right?

Again, as to assistant professors: Stanford gives them 45.8 per cent. of the full professor’s compensation; California, 49.4 per cent.; Cornell, 54.7 per cent.; Wisconsin, 59 per cent. and Harvard, 61.6 per cent. Here is a difference of opinion of 33.3 per cent. Which is right?

As to associate professors we have: Stanford, 63.4 per cent.; California, 68.8

per cent.; Wisconsin, 75 per cent. and Harvard, 81.6 per cent.—a difference of 30 per cent. Again, which is right?

Surely there should be some closer agreement than this on so definite a question.

Similar differences of opinion are very evident elsewhere in fundamental questions of administration. The student of these problems who has struggled with the difficulties of obtaining dependable information hails with delight the valuable material already gathered and published by the Carnegie Foundation. The wholesome publicity and chance for comparison thus given will lead to vital educational reforms and greatly improved efficiency of the entire higher educational system in America.

The following table based upon statistics published by the Carnegie Foundation in Bulletin No. 2 shows the nature of some of the queries which may be raised.

What is a proper proportion of total annual income to be expended for salaries for instruction? Is it 37 per cent., as Missouri makes it at one end, or twice that, as Columbia, New York University, Pennsylvania and Princeton seem to agree?

Recalling charts 13–17; should there be one full professor to forty students, as in Harvard College, or one to twice that number of students, as at California?

Looking at our table again. Considering the entire staff, is Johns Hopkins right with one member of staff for 3.7 students, or are Chicago, Nebraska, Ohio, Syracuse, etc., correct with four or five times as great a ratio as this? A difference of opinion of 500 per cent. is considerable.

Or again, can efficient instruction be provided at an entire expenditure per student year of \$97 or \$98, as Syracuse and New York Universities have it, or should one expend \$456 or \$479, as do Harvard

TABLE IV

	Annual Income	Annual Sal. App. for Inst.	Ratio Sal. Inc.	Total Students	Total Inst. Staff	Ratio Stud. Inst.	Income per Stud.	Sal. Exp. per Stud.	Salary per Mem- ber Inst. Staff
Columbia	\$1,675,000	\$1,145,000	0.683	4,087	559	7.3	\$409	\$280	\$2,050

California	844,000	408,000	0.484	2,987	350	8.5	282	137	1,180
Stanford ¹³	850,000	365,000	0.428	1,668	146	10.7	510	219	2,500
Toronto	610,000	324,000	0.532	3,498	368	9.5	179	93	881
Princeton	442,231	308,650	0.699	1,301	158	8.2	340	237	1,950
Mass. Institute	505,000	301,000	0.595	1,415	211	6.7	359	213	1,427
Minnesota	515,000	263,000	0.510	3,889	303	12.8	133	68	867
Ohio State	475,000	244,000	0.513	2,014	127	15.8	236	121	1,023
Nebraska	425,000	240,000	0.565	2,886	173	16.6	147	83	1,387
Missouri	655,000	239,110	0.372	2,070	144	14.3	317	115	1,600
McGill	425,000	225,000	0.518	1,163	191	6	365	194	1,176
N. Y. Univ.	303,500	220,000	0.725	3,110	211	14.7	98	71	1,043
Northwestern	491,132	218,151	0.445	2,485	261	9.5	198	88	835
Johns Hopkins	311,870	211,013	0.675	651	172	3.7	479	325	1,226
Syracuse	279,000	180,000	0.645	2,875	199	15.3	97	63	904
Temple C.	72,895	54,272	0.745	2,343	198	11.8	31	23	274

and Johns Hopkins?¹⁴ Again there is a difference of opinion of 500 per cent.

Or, looking at the expenditure per student per year for instructional salaries; which are right, Syracuse and Minnesota at \$63 and \$68 or Columbia and Johns Hopkins at \$280 and \$325, respectively?¹⁵ Again 500 per cent. difference.

In fact, the only uniformity appears to be in the difference of 500 per cent. Surely, our institutions can not vary as

¹³ Data for Stanford appear to need modification. \$365,000 includes appropriation for administration, library and instructional staffs, 1907-8. Annual register gives 1,751 students and 218 staff, 1907-8. Excluding assistants, average salary \$2,367; including assistants (as above), about \$1,500.

¹⁴ The figure of \$510 for Stanford includes extraordinary rebuilding expenses as well as sinking fund.

¹⁵ In the *Transactions of the Commonwealth Club of California*, October, 1907, Assistant Treasurer Crothers, of Stanford, gives the instructional salary expenditure per student, 1907-8, as \$176.51.

much as these figures seem to indicate—or do they?

Coming to the last column of our table, obtained by dividing the instructional salary expenditure reported, by the reported number of members of the staff, is an average salary of \$274 per year, as given by Temple College (by the way, what is Temple College?) about right? Are Northwestern, Minnesota, Toronto, Syracuse, Cornell right at \$835, \$867, \$881, \$904 or \$1,007, respectively? Or are Columbia and Chicago, at \$2,050 and \$2,400, more near a proper standard?

It is such inquiries as these which are inevitably raised by the interesting and valuable data given in the reports of the Carnegie Foundation. And along this line of interesting and valuable data should be included the following table from the annual report of the treasurer of Yale University.

We are just at the beginning of making a real study of the economics of our higher

TABLE V

*Expenditure and Receipts per Student in Various Departments of Yale University, for the Year 1907-8**

Department	No. of Students	Exp. per Stud.	Rec. per Stud.	Ratio Rec. Exp.
Graduate	357	\$159.45	\$ 40.17	25.2 per cent.
Academic	1315	339.56	152.27	44.8 per cent.
Shof. Scien.	948	279.66	160.25	57.3 per cent.
Theology	80	641.03		
Law	339	177.14	122.86	69.3 per cent.
Medicine	137	396.90	130.22	32.9 per cent.
Art	39	315.02	69.25	21.9 per cent.
Music	83	268.99	140.12	52.1 per cent.
Forestry	61	469.39	119.17	25.3 per cent.
All Departments	3359	296.85	113.25	44.9 per cent.

educational system. As a matter of mutual aid, as well as good faith, all chartered institutions should publish a complete annual financial statement.

And now, to sum up this survey, which has necessarily but touched upon main issues.

What are the conclusions to be drawn?

Considering the vast and growing army of students and the marvelous broadening of the field of study which is offered, the impossibility of the ideal of a university "where any person can find instruction in any study," unless it can command unlimited endowments, becomes sadly apparent. For, if it depends at all upon tuition fees and attempts to raise these to the actual cost of the yearly instruction, it will destroy the first part of its democratic ideal—some worthy persons will inevitably be excluded by the expense.

In the writer's judgment it can best fight off the evil day of financial or educational insolvency by frankly limiting its field. The term insolvency is used advisedly—for any institution which can only run by cashing in the loyalty of its employees through lamentably underpaying them, is no less than financially insolvent. And any institution which pre-

tends to and advertises educational resources which it does not possess is educationally bankrupt.

The trend is strong in the direction of limitation of field. Throughout the land we see a clearer and cleaner conception of the difference in nature between the college and university. For pedagogic, disciplinary and economic reasons this distinction is growing more and more marked and in obedience to them institutions are shaping their activities. The greatest educational reform going on in America to-day is involved in viewing our educational system, from the primary schools up, as a whole organism, each division having its distinct part to play, in regard both to its direct relation to the world at large and to its relation to the other parts. To arrive at the evident demand of the world at large with reference to higher education we may consider these facts: in 1905-6 with a population of 83,935,399 in the United States there were 279,270 students receiving higher instruction; the total number of degrees granted was 20,655, which included 1,386 masters of arts and 327 doctors of philosophy. Standing out most impressively we have the fact that a very small number of institutions of genuine graduate rank would suffice to fill the present needs of the nation. And it is precisely this work which is most expen-

* Report of the Treasurer of Yale University for the year ending June 30, 1908.

sive and in pursuit of which we find our institutions engaged in an undignified rivalry with vast expenditures caused by unnecessary duplications of staffs and plants. This is a waste to be stopped. We are dissipating our means and energies and in this the professors are their own worst enemies. Taking the liberty of quoting from a letter from President Eliot to the writer,¹⁷ touching upon this point we find:

There can be no doubt that the increase in university salaries has not kept pace with increased cost of living during the last fifteen years. At Harvard—and I believe at other American universities—the failure to make the rise of salaries keep pace with the rise in the cost of living has been due in part to the natural desire to increase the teaching staff in proportion to the increasing number of students, and also to the keen demand for an increased provision of costly apparatus for teaching, particularly in the sciences. At Harvard I have seen with great regret a large increase in the expenditures for all sorts of objects which are not for direct teaching, though in themselves useful and desirable. The scale of living for colleges as well as for families has distinctly increased of late years, and the adoption of this new scale has interfered with the adequate raising of teachers' salaries.

Although President Eliot here lays stress on costly scientific apparatus, it must be borne in mind that in a recent report he took his faculty to task for extravagant book lists for the library—delicately calling attention to the fact that the need for many of the books called for could not be so very urgent, since it took a considerable portion of the time of the library staff to eliminate from these order lists the names of volumes already in the library. And it would not be out of place to recall here certain figures from the tables previously quoted from the reports of the treasurer of Yale University showing that in the order of cost of instruc-

tion the departments stand—theology, forestry, medicine, academic, art and then Sheffield Scientific; the cost per student year in the latter being \$17.19 less than the average of all departments. We may sum up, that we are all equally offenders in extravagant and ostentatious expenditures.

Coming back to the lesson to be taught from the statistics of degrees granted in 1905-6, coupled with the waste involved in unnecessary duplication, we can foresee that the next great step in educational reform will be along the line of limitation of field, particularly in the differentiation of the college from the university.

The great demand of the nation to-day is for collegiate training—a great deal better teaching of fundamentals with a view toward developing character and capacity. And ninety-nine one-hundredths of our present institutions could well limit themselves to this field with vast improvement in our educational efficiency. One important reform which this step would bring with it would be a new recognition of the almost forgotten fact that the prime function of the teacher is to teach—thus leading to adequate recognition and reward of teaching ability and devotion to the students' good—rather than discrediting this type of loyal service as is now the case.

There is already a strong trend toward a limitation of function by the institutions to those courses in which they can afford to give thorough instruction, supplementing each other rather than unnecessarily overlapping. A few institutions of ample endowment may be able to carry on for some years longer the combined function of university and college, but in these we shall find a sharper and sharper division-line drawn between the college and university work, with a marked difference in the handling of the students,

¹⁷ In comment on advance sheets of some of the charts of this paper.

both pedagogic and disciplinary. Still fewer, with the men, means and reputation, say half a dozen in our whole country at first, will bravely lop off all collegiate work as soon as it is adequately provided for elsewhere and stand forth as full-fledged *universities*—places for the purposes of true advanced education, for real (not sham) investigation, and for the training of leaders in thought, science and action. Our nation does not yet seem to make a strong demand for many of these, judging by recent experience. What will probably take place, along with more efficient instruction, will be to make the break between collegiate and university work at the end of the present sophomore year as the Germans practically do. There are sound reasons for doing this both from educational and from administrative standpoints, and to these may be added the strong economic argument that it will place our young men and women—quite as well trained as our present college graduates—in the world of outside activities two years earlier in their lives.

As to salaries, with these reforms carried out, there can be no doubt of a continuation of the present trend toward improvement with a hope of an ultimate scale permitting a standard of living within the line of suitable dignity and comfort. The writer would again draw attention to the fact, overlooked too long, that the instructorship is the real key to the situation of the improvement in higher instructional efficiency, and that any fundamental improvement in conditions must be begun in the treatment of this rank. In disclosing the real state of affairs and in guiding the institutions toward a closer cooperation, and unification into an efficient whole, the reports of President Pritchett, of the Carnegie Foundation, have already proved to be of extreme value. Further reports along the lines

already indicated will undoubtedly but add to the indebtedness of the educational world to this foundation. With its trained staff and financial support it can carry out investigations which, even with the greatest industry and devotion, would be impossible of achievement through individual effort.

As a final paragraph, the writer would call the attention of his fellow teachers to the inspiring vision of this vast army of young men and women coming forward for training for the duties of life. Well may we conceive a new respect for the importance and significance of our calling, and in all sincerity and humility dedicate ourselves afresh to a life of unselfish service in the cause of humanity; for to our hands is entrusted no less a power than that of effectively molding the controlling ideals of our nation's immediate future. Bacon says:

We advise all men to think of the true ends of knowledge, and that they endeavor not after it for curiosity, contention or the sake of despising others, nor yet for reputation or power or any such inferior considerations, but solely for the occasions and uses of life.

The great heart of America is sound; her ills of haste, diffusion and superficiality are curable. Humanly speaking, the key to the solution of all her problems lies in the substitution of trained, clear thought-processes for the still too prevalent slovenly-mindedness.

GUIDO H. MARK

STANFORD UNIVERSITY

SCIENTIFIC NOTES AND NEWS

A COMPLIMENTARY dinner was given on April 17 at Hotel Somerset, Boston, in honor of the seventieth birthday of Professor F. W. Putnam, since 1886 professor of American archeology and anthropology at Harvard University and for twenty-five years permanent secretary and later president of the American Association for the Advancement of Science.

A large volume of anthropological essays contributed by various friends and associates was presented, and numerous letters and telegrams of congratulation were received from scientific bodies in this country and in Europe.

We much regret to learn that Professor Simon Newcomb, who had been recovering from an operation performed in January, has been compelled to return to the Johns Hopkins Hospital.

At a convocation of McGill University to be held on the occasion of the opening of McDonald College at St. Anne's on June 3, the degree of LL.D. will be conferred on the Hon. James Wilson, secretary of agriculture; Dr. James Earl Russell, dean of Teachers College, Columbia University; Mr. Gifford Pinchot, chief forester; Dr. D. McEachern, former dean of the faculty of comparative medicine of McGill University, and Dr. James W. Robertson, principal of Macdonald College.

The Cullom Gold medal of the American Geographical Society of New York, awarded to Professor W. M. Davis in the spring of 1908, was presented to him at the meeting of April 20, 1909, when he lectured before the society on the "Lessons of the Colorado Canyon."

PROFESSOR A. LAWRENCE ROTCH has recently been elected an honorary member of the Austrian Meteorological Society.

At the Washington meeting of the American Physical Society, Professor Max Planck, of the University of Berlin, now in this country to lecture at Columbia University, was elected an honorary member.

To Professor L. H. Friedburg his colleagues of the chemistry department of the College of the City of New York, gave a dinner on May 1 in celebration of the fortieth anniversary of his receiving the doctor's degree at Göttingen.

PROFESSOR CHARLES B. RICHARDS, for the past twenty-five years head of the mechanical engineering department in the Sheffield School of Yale University, has signified his intention of retiring.

THE office of the superintendent for suppressing the gypsy and brown-tail moths by an act of the general court of Massachusetts

has been combined with the office of state forester under the title of the latter. Governor Draper and his council appointed Mr. F. W. Rane to the new position on April 14 at a salary of \$5,000. The office of state forester has been moved from the State House to No. 6 Beacon street.

MR. H. FOSTER BAIN has become associate editor of the *Mining and Scientific Press* at San Francisco. Mr. T. A. Rickard, editor of the journal, is about to start a monthly mining magazine at London, England.

PROFESSOR ARTHUR HOSKINS, professor of mineralogy in the Colorado School of Mines, was seriously injured by a collision of the train carrying 135 members of the senior class of the School of Mines on a trip of inspection to Utah and Montana.

PROFESSOR WALLACE C. SABINE, dean of the Graduate School of Applied Science, of Harvard University, sailed from New York on April 29 for Naples. He goes in the interests of the university to observe the equipment and methods of various technical schools in Europe and to study the acoustics of some of the buildings. He will visit technical schools at Turin, Zurich, Aachen, Munich, Leipsic, Charlottenburg, Breslau, Paris, London, Manchester, Leeds and other places.

DR. ROBERT KENNEDY DUNCAN, professor of industrial chemistry at the University of Kansas, sailed on May 15 for Europe to attend the International Congress of Applied Chemistry.

DR. A. HRDLICKA, of the U. S. National Museum, has returned from a five months' trip to Egypt and Europe.

DR. WARREN D. SMITH has resumed his duties as chief of the Mining Division of the Bureau of Science, Manila, after ten months spent in America and Europe in working up Philippine material. He spent some time in Leiden in comparing Philippine fossils with Dr. Martin's Javan types. While in London Dr. Smith was elected a fellow of the Royal Geographical Society.

PROFESSOR J. MARK BALDWIN, of the Johns Hopkins University, has been giving courses under the auspices of the Mexican Department of Public Instruction on University

Organization and on Scientific Psychology. According to the *Mexican Daily Record*, in one of his lectures, attended by the minister of public instruction and fine arts, he advocated the union of the professional schools in the City of Mexico and the establishment of a university under the auspices of the government.

DR. L. A. BAUER gave the following course of lectures on terrestrial magnetism at the Johns Hopkins University, May 4-7: "The Earth's Magnetism and its Variations"; "Solar Activity and Magnetic Storms"; "Magnetic Surveys"; "Methods and Results."

ON May 4 Professor Svante Arrhenius began a course of two lectures at the Royal Institution on "Cosmogonical Questions." These are the Tyndall lectures. The Friday evening discourse on May 7 was delivered by Major Ronald Ross, on "The Campaign against Malaria," on May 14 Professor George E. Hale will lecture on "Solar Vortices and Magnetic Fields."

LIEUTENANT E. H. SHACKLETON will describe his Antarctic expedition at a meeting of the Royal Geographical Society to be held in the Albert Hall on June 24.

A TABLET in memory of the late President Thomas M. Drown has been placed on the walls of the chemical laboratory of the Massachusetts Institute of Technology. A similar tablet will be placed in Drown Memorial Hall of Lehigh University.

THE sixtieth congress appropriated, as has been noted here, five thousand dollars for the erection of a suitable memorial to Major J. W. Powell, to be placed on the brink of the Grand Canyon of the Colorado. For the purpose of complying with the will of congress in this behalf, the Secretary of the Interior asked a committee consisting of W. H. Holmes, chairman, H. C. Rizer and C. D. Walcott to assist him in determining the character of the monument and in selecting the site. At the earnest solicitation of numerous old-time associates of Major Powell, this committee has consented to initiate a movement among his friends for the

erection of an appropriate monument over his grave at Arlington National Cemetery, which remains as yet unmarked. The character of the monument will not be decided upon until the fund has been raised, but the committee will be glad to receive from contributors suggestions relating thereto. Subscriptions should be sent to Colonel H. C. Rizer, U. S. Geological Survey, Washington, D. C.

THE bill to establish a state geological survey in Tennessee has passed both houses of the legislature by a large majority. The bill provides for a commission composed of the governor, secretary of agriculture, state inspector of mines and the heads of the three leading educational institutions of the state, the University of Tennessee, Vanderbilt University and the University of the South (Sewanee). The act carries an appropriation of fifteen thousand dollars for each of the years 1910 and 1911. In view of the unusual expenditures for 1909 the appropriation was not made available until 1910.

FOR the second time within three months fire threatened with destruction on May 9 the building in Washington in which the Geological Survey is housed. The blaze was extinguished, not, however, until the chemical laboratory had been destroyed and valuable maps and charts stored in the building had been again damaged by water. It is not known how the fire originated, but it is practically certain that crossed electric wires were the cause of the trouble, as they were of the blaze three months ago.

THE seventh annual meeting of the Nantucket Maria Mitchell Association was held in Boston on April 28. In addition to routine business, a committee was appointed to collect twenty-five thousand dollars, the income of which shall be used to meet the expenses of an astronomical observer; it is proposed that said fund shall be known as the Memorial Research Fellowship of the Nantucket Maria Mitchell Association and shall provide for the appointee several months study in one of the larger universities, the remaining working months of the year to be given to the Memorial Observatory on Nantucket, where original research work shall be accomplished together

with instructions to classes or individuals. The appointee shall preferably be a woman if equally competent with other applicants, and the fellowship shall be awarded by a committee of six, composed of the president of the association, the chairman of the observatory committee and four others to be named by the president. The committee appointed for this service is Chairman, Professor Mary W. Whitney, Vassar College; Miss Annie J. Cannon, Harvard Observatory; Miss Caroline E. Furness, Ph.D., Vassar College; Mrs. Thomas W. Sidwell, Washington, D. C.; Dr. Emma B. Culbertson, Boston, and Mrs. Charles S. Hinchman, secretary, 3635 Chestnut street, Philadelphia, Pa.

UNIVERSITY AND EDUCATIONAL NEWS

THE recent Minnesota legislature appropriated to the State University \$2,150,000 for the biennial period. This is in addition to the mill tax amounting to \$235,000 annually. Of the appropriation made by the legislature, \$190,000 is for support in 1909-10 and \$200,000 support for 1910-11. The sum of \$350,000 is appropriated for campus extension, and nearly \$1,000,000 for new buildings. The latter are to include a general medical building and an anatomical building, each to cost \$200,000.

THE trustees of Columbia University announce that \$500,000 had been secured for the erection of Kent Hall and work on the new law school building will soon begin. Other gifts announced were \$30,000 for general university purposes and \$5,000 for the department of pathology, both being anonymous.

A FUND of \$100,000 has been collected for Middlebury College, of which \$25,000 has been given by Dr. D. K. Pearson.

MR. JOHN R. LINDGREN has given \$25,000 to the Northwestern University to establish a fund for the promotion of peace.

THE new hall of engineering of Northwestern University was dedicated on May 7, when addresses were made by Professor John F. Hayford, director of the College of Engineering and Mr. C. W. Baker, editor of *The Engineering News*.

THE inauguration of Dr. Abbott Lawrence Lowell, as president of Harvard University, and the attendant ceremonies will be held on October 6 and 7, 1909.

AT Columbia University Dr. A. P. Wills, adjunct professor of mechanics, has been appointed professor of mathematical physics, to succeed Professor Richard T. Maclaurin, who will become head of the Massachusetts Institute of Technology. Dr. Bergen Davis has been appointed adjunct professor of physics to fill the vacancy arisen through the death of Professor Tufts. Dr. Geo. B. Pegram has been promoted to an adjunct professorship in the same department. Dr. Hugh Angus Stewart, of Edinburgh and recently of the Johns Hopkins University, has been called to an adjunct professorship of pathology in the College of Physicians and Surgeons.

THE new professorship in the department of teaching of the University of Vermont has been filled by the appointment of Dr. J. F. Messenger, A.B. (Kansas), A.M. (Harvard), Ph.D. (Columbia), now professor of pedagogy in the Virginia State Normal School at Farmville.

DISCUSSION AND CORRESPONDENCE

OCCURRENCE OF THE KILLER WHALE (*Orcinus orca*) ON THE NEW JERSEY COAST

TO THE EDITOR OF SCIENCE: Neither of the two zoologists, Messrs. Rhoads and Stone, who have recently published extensive catalogues of the vertebrate fauna of New Jersey, records any instances of the stranding of killer whales on the coast of that state. Mr. Rhoads remarks of them (1903):

While often found off the New Jersey coast, there seem to be no records of its stranding, or being captured.

In view of this circumstance, it may be of some interest to note that the National Museum has obtained the skull and other parts of the skeleton of a killer whale which stranded at Barnegat, N. J., in January, 1909. The animal was at first reported to be a strange creature, of a most extraordinary kind, with hair, claws, a long neck, etc., but upon receipt of the skull it was at once seen that these characters were imaginary. The specimen was reported to be about thirty feet

long, and the skull proves it to have been an old individual.

Killer whales rarely strand on the Atlantic coast of the United States, and, aside from the individual just mentioned, there are, so far as I am aware, no specimens from definite localities on our Atlantic seaboard in any museum. Two killers stranded at Eastport, Me., in 1902, and were reported on by myself, and another was obtained at Portland, Me., in 1904, but the bones were not, I believe, preserved in either instance.

F. W. TRUE

April 6, 1909

THE PTARMIGAN AND THE SONNET

TO THE EDITOR OF SCIENCE: Probably some readers of Mr. Clark's letter in SCIENCE, March 26, were no more amused at that queer ptarmigan than at his naming a blank-verse poem a "sonnet." "It is written that the shoe-maker should meddle with his yard and the tailor with his last, the fisher with his pencil and the painter with his nets," to the entertainment of men ever since old Capulet's Peter.

H. L. SEAVER

JOHANNSEN'S DETERMINATION OF ROCK-FORMING MINERALS

SINCE the book review in this journal of January 1, 1909, p. 32, the author has arranged with the publisher to indent and thumb reference the different parts of the text-book. This has added greatly to its convenience and efficiency.

L. McI. L.

FAMILY RECORDS

RECOGNIZING the great importance to humanity of a knowledge of the method of inheritance of physical and mental human characters the Station for Experimental Evolution is attempting to collect data for study and requests the assistance of persons who will volunteer to fill out a pamphlet form with blank spaces for data on some 36 characters in three generations of their family. These "Family Records" are sent in duplicate; one to be retained by the collaborator for his own

use, the other to be mailed to the station. A request by postal card for these records will receive an immediate response.

C. B. DAVENPORT

COLD SPRING HARBOR, N. Y.

SCIENTIFIC BOOKS

Handbuch der Klimatologie. Band I. *Allgemeine Klimalehre.* Dritte wesentlich umgearbeitete und vermehrte Auflage. Von Dr. JULIUS HANN. 8vo, pp. xiv + 394, figs. 22. Stuttgart, J. Engelhorn. 1908.

1883, 1897 and 1908 are three important dates in the progress of climatology. They are the years in which were published the first, second and third editions of Hann's "*Handbuch der Klimatologie.*" Few text-books, in any one science, are so widely known to all men of science as Hann's famous "*Handbuch.*" The second edition was so complete and so satisfactory that it was practically impossible to find fault with it in any important respect. Yet the new edition is an improvement upon the former one. The size of the page has been somewhat increased, a fact which is of special significance when the climatological tables, which will be necessary in the second and third volumes, are printed. The arrangement by books, chapters and sections, as well as the many new paragraph headings, help very much to make the volume more convenient for general use. All the important literature bearing dates since the publication of the second edition is mentioned, or summarized, in the new edition. Indeed, this book is much more than a text-book. Its numerous and well-selected bibliographic lists make it truly an encyclopædia.

Additions have been made throughout the volume. We note, especially, the newly introduced or the more extended discussion, of sensible temperatures; of the relative humidity indoors; of the nature and measurements of solar radiation; of the introduction of the cyclonic unit into climatological investigations; of the reduction of temperature observations to uniform periods of time; of the zonal distribution of the climatic elements, and of the classifications of the zones. Many persons will naturally turn to the chapters on

the influence of forests on climate, and on changes of climate, to see what the greatest authority on climatology has to say on these subjects. Regarding the former, Hann says that the influence of forests upon rainfall is a slight one. Regarding the latter, while granting that Stein, Huntington and others have shown that there is a general desiccation going on in Asia, the author adds: "How far in all these accounts we have to do with a progressive desiccation, and how far with climatic oscillations, is still a question." In other words, there is as yet no sufficient evidence for believing in considerable *permanent* changes. Oscillations, yes, some of longer, others of shorter periods; but permanent progressive changes, no, not yet.

The teacher of climatology will feel safe and sure with Hann's book on his study shelf, close at hand. The man of science, in whatever field he may be working, who needs the fullest, latest, most authoritative information on climatology, will find in Hann's new volume what he seeks, and he will find it clearly set forth.

The remaining volumes, dealing with the special climates of the different parts of the world, will be published shortly.

R. DEC. WARD

Reservoirs for Irrigation, Water Power and Domestic Water Supply. By JAMES DIX SCHUYLER, M.Am.Soc.C.E., M.Inst.C.E., etc. Second edition revised and enlarged. Bound in cloth; dimensions, 6½ by 10½ inches. Pp. 573; illustrations 381; folding plates 6. Price, \$6.00. New York, John Wiley and Sons; London, Chapman and Hall, Ltd.

The growing importance of storage reservoirs and their appurtenant structures in the development of domestic water supplies, hydraulic power plants and irrigation projects warrants the revision and enlargement of this already useful work. The scarcity of water furnished by the normal flow of streams for irrigation in the arid regions; the increasing demand for water power due to the decreasing coal supply and the increasing possibilities of electric power and the sanitary needs of the many growing towns and cities throughout the

entire country are requiring wide information on the subject of water storage and water-storage structures. This information abounds in the book under review, as may be inferred from its chapter subjects, the titles of which are as follows: Rock-fill Dams; Hydraulic-fill Dams; Masonry Dams; Earthen Dams; Steel Dams; Reinforced Concrete Dams, and Miscellaneous. In these chapters are discussed individually more than 200 important dams, of which the majority are of the masonry type. However, over a score each of rock-fill, hydraulic-fill and earthen dams and nearly a half score of steel and reinforced concrete dams are described in detail.

The style and arrangement of subject matter of the book lack uniformity and its substance is rather a collection of facts relating to dams and reservoirs than a scientific treatise thereof. The author has included but little of the principles of design and construction except as incident to description. The work is therefore better adapted to use for reference than for study. It is an excellent memory storehouse for the practising engineer. Such works, although not forming the highest type of engineering literature, are none the less essential parts thereof, and are especially valuable as sources from which to draw inferences from basic facts.

The first edition of this work found its way into the libraries of many engineers and the second edition is certain to find a still greater circulation. Sufficient new and rewritten material has been incorporated into the text to make the book essentially a new work. In addition to the new and revised subject matter the book contains 234 new cuts and photographs and 3 plates. The work will, therefore, be equally of interest to those familiar and unfamiliar with the first edition.

F. W. HANNA

U. S. RECLAMATION SERVICE

SCIENTIFIC JOURNALS AND ARTICLES

The American Naturalist for April opens with a paper on "Heredity of Hair Color in Man," by Gertrude C. and Charles C. Davenport. This article includes a number of tables showing the distribution of color in the off-

spring of parents with hair of a given color, the authors concluding that heredity in hair color is alternative, and that the known facts fit Mendel's law rather than Galton's. G. H. Parker discusses "A Mechanism for Organic Correlation," showing the influence of the secretions of various glands in bringing about marked changes in certain portions of the body—these secretions are termed "hormones," and in some instances are absolutely essential to life. Under "Recent Advances in the Study of Vascular Anatomy," John M. Coulter deals with "Vascular Anatomy and the Reproductive Structures." Raymond Pearl presents "A Note on the Degree of Accuracy of the Biometric Constants" and O. F. Cook a communication on "Pure Strains as Artifacts of Breeding."

Bird-Lore for March-April has the following articles: "Chickadee All the Year Round," by Mary C. Dickerson; "A Second Season of Bluebird Tenants," by Marian E. Hubbard; "A Special Bird Blind," by E. J. Sawyer; "Eggs of a Flicker found in a Strange Place" (on the ground), by William Brewster; "Where Does the Male Horned Lark stay at Night?" by R. W. Hagner, and the first paper on "The Migration of Vireos," by W. W. Cook. There is a striking illustration of a drumming ruffed grouse, photographed from life by C. F. Hodge.

In *The American Museum Journal* for April Charles W. Mead gives some interesting notes of the Andaman Islanders and their customs under "A Collection from the Andaman Islands." W. D. Matthew tells of "The Oldest Land Reptiles of North America" and there is a note, with an illustration of a fine "Group of Peculiar Mollusks," *Vermicularia nigricans*.

The Bulletin of the Charleston Museum for March notes "The Needs of the Museum" in the way of money for the purchase of cases and installation of specimens. The city of Charleston is doing all it possibly can and private individuals must do the rest. In the south, where so large a proportion of the population is negroes, the number of actual taxpayers is vastly less than the number of in-

habitants and this is the case in Charleston. The second part of the "Local Fauna" completes the list of birds, 216 species, observed in the vicinity of Charleston.

The Johns Hopkins University Circular for January contains the addresses given at the memorial meeting in honor of Dr. W. K. Brooks and also the charming "Biographical Sketch" by E. A. Andrews, reprinted from *SCIENCE*. It also contains the addresses commemorative of Dr. Gilman.

THE EPIDERMIS OF AN IGUANODONT DINOSAUR

We owe to Charles H. Sternberg and his son George F. Sternberg the welcome discovery of the epidermal markings of an Upper Cretaceous Iguanodont. The discovery was made August, 1908, in the region of Converse County, Wyo., made famous by the explorations of Hatcher for remains of *Ceratopsia*. This *Triceratops* Zone, originally designated as the *Ceratops* Zone, is divided, like that of the Hell Creek Basin in Montana, into successive layers of sandstones and clays. The present specimen¹ was found near the summit of the basal sandstones, and is provisionally identified by Mr. Barnum Brown who is making a special study of these dinosaurs, as belonging to the species *Trachodon annectens* Marsh.

As found, the entire animal lay in a normal position on its back and completely encased in the impression of its epidermal covering as far back as the posterior portion of the pelvis and extremities of the hind limbs, which had been cut off and removed by erosion. The left fore limb was outstretched at right angles to the body, while the right fore limb lay stretched over the under surface of the head. The manus is completely encased in the integument, and was thus web-footed—adding another analogy to the *Anatidæ*. The head was sharply bent around to the right side (the left side as seen from above). The scapulæ were closely pressed to the sides and probably in normal position, as well as the

¹ This unique specimen has been added to the Jesup collection of reptiles and amphibians, through the liberality of Mrs. Morris K. Jesup.

coracoids and sternal plates. The upturned ribs were also without compression, affording a normal section of the chest. The hind limbs were drawn up and doubled on themselves. The animal thus occupied a space of 10×12 feet. The precise position of the elements of the pectoral arch and chest is not the least important feature of the discovery.

The most important feature is the complete encasement of all parts of the body which are preserved in a natural cast of the impression which the epidermis made upon the matrix, affording for the first time complete data as to the skin structure of the *Iguanodonts*. Some of the outlying parts of the epidermis, especially along the neck frill, at the extremities of the manus, and along certain border regions, were cut into apparently before it was realized that the epidermal cast was preserved; but at many important points these impressions are perfectly shown, especially on the throat and anterior part of the neck, on the arms, and fore limbs, on the entire right side of the body, and over a large part of the ventral surfaces, including the axillary regions and especially over the abdomen. Most remarkable is the inflection of the skin like a curtain along the lower border of the ribs, over the entire abdominal region without a single break, with brilliant impressions of the scale pattern. Equally significant are the sharp skin folds over the sides of the body and in the axillæ, at the throat, and along the flexor surfaces of the arms. This abdominal infolding, the close appression of the skin to the surface of the bones, the sharp transverse folds, all indicate that after death the body had been exposed for a long time to the sun, that the muscles and viscera had become completely dehydrated; in other words, the body had become thoroughly dried and mummified, while the epidermis became hardened and leathery under the action of the sun. In this condition the dinosaur mummy had been caught in a freshet and rapidly buried in fine river sand which took a perfect cast of the epidermal markings before the tissues disintegrated under the solvent action of the water.

The first and most surprising impression is that the epidermis is extremely thin, and that

the markings are excessively fine and delicate for an animal of such large dimensions. There is no evidence in any part of the epidermis either of coarse tubercles or of overlapping scales. In all parts of the body observed it is entirely composed of scales of two kinds: (1) larger pavement or non-imbricating scales, (2) smaller tubercular scales.

The former are perfectly smooth and non-imbricating, like the pavement head scales on the *Lacertidæ*. As grouped in clusters or rosettes they are rounded or irregularly polygonal. Over the throat, neck, sides and ventral surface these clusters are regularly disposed in definite patterns, separated by areas of finer tubercular scales, but in the tail, as indicated in another specimen, it is probable that the cluster arrangement disappears and that the entire tail is covered with the tessellated or pavement pattern, including scales of larger size, although this may be a matter of specific difference. In many existing lizards we observe a strengthening of the scales in the caudal region, and the vigorous use of the tail among *Iguanodonts* as a balancing and perhaps partly as a swimming organ, would lead us to expect stronger scales in the tail region.

As observed on the sides of the body just above the scapula, the pavement scale clusters are 3.5 to 4.5 cm. in diameter. In the center of the cluster the scales are about .5 cm. in diameter, and toward the borders they diminish to .35 cm., while the outlying tubercular scales number six or seven per centimeter. These clusters run in definitely arranged patterns, which will be fully described in a later communication, from the sides around the under surface of the body.

On the side of the throat in the region just back of the quadrates are much larger clusters of these flattened scales, but beneath the throat there is again observed the alternation of the clusters with intermediate tubercular areas. A large cluster is beautifully preserved on the upper arm, half way between the elbow and shoulder, but the lower arm seems to be chiefly covered with the small tubercular scales, although some pavement scales may also be observed. On the forearm the skin

is thrown into diagonal folds, but seems to preserve some of the muscular contour.

On the tail of another specimen of *Trachodon*, from the American Museum Cope Collection, the entire epidermis is covered with flattened scales of larger size, nearly a centimeter in diameter.

This disposition of the scales into the larger pavement groups and smaller tubercular areas is unlike that observed by the writer in any lacertilian; it appears to be unique. In a second paper the longitudinal and perpendicular arrangement of the clusters will be more fully made out.

Mr. Sternberg has added another of his important contributions to science through the fortunate discovery of this unique specimen, in a geologic region which was very generally considered as thoroughly prospected out.

HENRY FAIRFIELD OSBORN

BOTANICAL NOTES

SHORT NOTES

IN the March number of the *Journal of Botany* R. F. Rand begins his altogether interesting "Wayfaring Notes in Rhodesia" which remind one of the notes made by the traveling botanists of a century or so ago. Here one finds morphological, ecological, taxonomic and critical notes delightfully commingled.

AKIN to the foregoing are the notes on English plants made by Matthew Dodsworth, a seventeenth century botanist, now first published in the *Journal of Botany* for March, by the editor. It is interesting to note such names as "Wild Williams" (for *Lychnis flos-cuculi*) and "Woodbind" (for Woodbine). A couple of letters to Plukenet are dated 1680 and 1681.

IN a recent number of the *Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten* (Bd. XXII., Abt. 2) Dr. O. Jensen, of Copenhagen, proposes a new classification of the bacteria based upon their activities. He recognizes eleven families, as follows: *Acidobacteriaceae*, *Actinomycetes*, *Thiobacteriaceae*, *Rhodobacteriaceae*, *Trichobacteriaceae*, *Luminobacteriaceae*, *Reducibacteriaceae*,

Acidobacteriaceae, *Alkalibacteriaceae*, *Butyrobacteriaceae*, *Putrobacteriaceae*. A chart showing the relationship of these families and the genera they contain accompanies this quite suggestive paper.

AN interesting paper on the temperature relations of foliage-leaves in the February number of the *New Phytologist* is likely to be somewhat disconcerting to those botanists who still speak of the "cool leaves"—made so by transpiration. Not only are leaves shown to have a high internal temperature in the sunlight, but Molisch has found that leaves may have a high temperature due to respiration.

ELMER D. MERRILL, of the Biological Laboratory of the Bureau of Science, Manila, has published many important botanical papers during the past two years in the *Philippine Journal of Science*, among which are the following which have been issued as separates: Index to Philippine Botanical Literature; The Flora of Mount Halcon, Mindoro; Additional Identifications of the Species described in Blanco's Flora de Filipinas; Philippine Plants collected by the Wilkes United States Exploring Expedition; New Philippine Plants from the Collection of Mary Strong Olemens; New or Noteworthy Philippine Plants; The Oaks of the Philippines (*Castanopsis*, 1 sp.; *Quercus*, 17 sp.); Philippine Ericaceae (*Rhododendron*, 16 sp.; *Vaccinium*, 19 sp.; *Gaultheria*, 2 sp.; *Diplycosia*, 2 sp.); On a Collection of Plants from the Batanes and Babuyan Islands.

FROM the Philippine Bureau of Forestry we have the Annual Report of the director, Major George P. Ahern, and a paper by the same author, entitled "A Few Pertinent Facts concerning the Philippine Forests and Needs of the Forest Service, that should interest every Filipino." In the latter he urges the Filipinos to educate their children for the public service, especially as foresters, and calls attention to the 60,000 square miles of public forests and the advantageous position of the islands for the supply of lumber to the far east. In another bulletin (No. 9) W. I. Hutchinson calls attention to a Philippine

substitute for lignum vitae in the heartwood of *Xanthostemon verdugonianus*, which weighs 77 pounds per cubic foot. The tree is large, with a diameter of 45 inches, and a length of stem of 25 to 30 feet. It occurs in the southern islands of the archipelago.

SPECIAL ARTICLES

A FOSSIL GAR-PIKE FROM UTAH

SOME time ago Professor R. D. George obtained in Utah a fine specimen of *Lepisosteus* preserved in a block of limestone. The fossil is of particular interest because the stone is being quarried by the Western Lithographic Stone Company, yielding slabs highly serviceable for lithographic purposes. The age of the formation had not been determined until the fish was examined, but it is now safe to say that it is Middle or Lower Eocene. The specimen was obtained twelve feet from the surface, three miles northwest of Tucker, Utah. It lacks the head, but is otherwise in very good condition. In all respects, it agrees excellently with *Lepisosteus simplex* Leidy, as described and figured by Eastman.¹ Eastman's excellent figure, except for having the head, might almost have been taken from our specimen. The smooth scales, with occasional minute pits, are in exact agreement, as are the characters of the fins, etc.

L. simplex was found in the typical Green River locality in Wyoming, according to Eastman, though Hay ascribes it to the Bridger Eocene. There is a species described from Utah, *L. cuneatus* (Cope), which has smooth scales, and it is at least very much like *L. simplex*. This *L. cuneatus* comes from the Manti shales, Manti being some fifty miles south-southwest of Tucker. Eastman (*loc. cit.*) ascribes this to the Miocene, but Cope considered it Eocene, and it has been held that the Manti shales are of the same age as the Green River. It may be that the true Green River extends from Wyoming to central Utah, and that *L. cuneatus* is the same as *L. simplex*.

THE NUCLEATION OF A CLOSE LECTURE ROOM

RECENTLY, at the request of Professor Barus, I made a series of measurements on the nuclei in the air of a crowded lecture room. There were over a hundred students in attendance and the ventilation was not sufficiently brisk to obviate the occurrence of somewhat offensive closeness at the end of the hour. The object of the investigation was to determine whether any solid or liquid nuclei were thrown off by the many lungs in action, sufficient to be detected by the coronas of the fog chamber in the presence of the natural nucleation (largely inorganic) of the lecture room.

The method of investigation consisted in aspirating the air of the room continuously through the fog chamber and examining it by exhaustion from time to time. The result may best be given graphically by laying off the nuclei in thousands per cubic centimeter in a way to show their variation in the lapse of minutes of time.

The figure begins with a moderate measure of dust during the desultory entry of the members of the class. But throughout the lecture hour the nucleation diminishes. Evidently there is subsidence of dust (in part into the lungs of the students who virtually cushion the floor), but no corresponding evolution of nuclei as resulting from the respiration of this animated carpet. At the close of the lecture, when the class rises hilariously as a body to depart from the place of torment, they literally raise the dust again, in much larger quantity than on entering.

Unfortunately it is impossible to separate the organic from the inorganic dust content of this atmosphere for the present purposes. The only conclusion attainable is, therefore, that there is no appreciable evolution of non-gaseous matter, but rather an absorption of nuclei

by the respiration of a hundred active lungs, even when the closeness of the air becomes oppressive. The possibility of recognizing spore production, however minute, from cultures made in dust-free air, may not be without interest.

SOCIETIES AND ACADEMIES

THE AMERICAN MATHEMATICAL SOCIETY

The one hundred and forty-third regular meeting of the society was held at Columbia University on Saturday, April 24, 1909, extending through a morning and an afternoon session. The attendance was about thirty-five persons, including twenty-six members of the society. President Böcher occupied the chair, being relieved at the afternoon session by Vice-President Kasner. The council announced the election of the following persons to membership in the society: Miss W. B. Bauer, High School, Topeka, Kan.; Mr. W. W. Denton, University of Illinois; Mr. Meyer Gaba, University of Kansas; Professor W. H. Garrett, Baker University; Miss S. E. Graham, High School, Topeka, Kan.; Mr. G. F. Gundelfinger, Sheffield Scientific School; Professor W. A. Harshbarger, Washburn College; Mr. L. T. W. Hogrefe, Milwaukee, Wis.; Professor L. A. Howland, Wesleyan University; Mr. George Melcher, State Normal School, Springfield, Mo. Three applications for membership in the society were received.

Professor H. S. White was reelected a member of the editorial committee of the *Transactions* for a term of three years beginning October 1, 1909.

The following papers were read at this meeting:

R. D. Carmichael: "On certain functional equations."

R. D. Carmichael: "Note on some polynomials related to Legendre's coefficients."

W. H. Jackson: "A theorem concerning simple continued fractions."

W. H. Jackson: "Shadow rails."

L. P. Eisenhart: "The twelve surfaces of Darboux and the transformations of Moutard."

W. F. Osgood: "On Cantor's theorem concerning the coefficients of a convergent trigonometric series, with generalizations."

L. S. Dederick: "Certain singularities of transformations of two real variables."

Paul Saurel: "On Fredholm's equation."

J. E. Wright: "On abelian functions of genus 3."

J. C. Morehead: "A simplification of Lagrange's method for the solution of numerical equations (second paper)."

A. S. Chessin: "On gyroscopic couples."

Edward Kasner: "The interpretation of differential equations in line coordinates."

E. D. Roe, Jr.: "On the extension of the exponential theorem."

Mr. Dederick's paper was presented to the society through Professor Bouton. In the absence of the authors Mr. Dederick's paper was read by Professor Böcher, and the papers of Professors Carmichael, Saurel, Chessin, Kasner and Roe, and Dr. Morehead were read by title.

The Chicago section of the society held its spring meeting at the University of Chicago on Friday and Saturday, April 9-10. The summer meeting and colloquium of the society will be held at Princeton University in the week September 13-18.

F. N. Cole,
Secretary

THE UTAH ACADEMY OF SCIENCES

The second annual meeting of the Utah Academy of Sciences was held in the auditorium of the Packard Library, Salt Lake City, on Friday evening, April 9, and Saturday afternoon, April 10.

The Friday evening meeting was a "Darwin Centennial" memorial, as indicated by the program:

"Darwin the Man," by Professor W. W. Henderson.

"Factors in Zoological Evolution," by Dr. John Sundwall.

"Factors in Botanical Evolution," by Dr. C. T. Vorhies.

Discussion, led by Dr. E. D. Ball.

The Saturday afternoon program consisted of the following papers:

"The Adaptation of Insects, with Special Reference to Arid Conditions," by Dr. E. D. Ball.

"The Alfalfa Leaf Weevil," by Professor E. G. Titus.

"The Honey Ants of Utah," by A. O. Garrett.

"Orbital Glands of Amphibians," by P. G. Snow.

"Note on Geological Survey Bulletin No. 371," by J. B. Forrester.

"High Temperature Measurement," by Dr. L. W. Hartman.

"Pottery Glaze Coloring," by A. F. Greaves-Walker.

"The Valuation of Fuel according to Analysis," by Dr. William Blum.

"Philippine Birds," by Chaplain Joseph Clemens, Ft. Douglas.

At the business session, the following officers were elected for the ensuing year:

President—Dr. W. O. Ebaugh, University of Utah.

First Vice-President—Dr. E. D. Ball, Utah Experiment Station.

Second Vice-president—W. D. Neal, Weber Stake Academy.

Secretary—A. O. Garrett, Salt Lake High School.

Treasurer—Dr. Philena Fletcher Homer, Brigham Young University.

Councillors—Professor J. L. Gibson, University of Utah, Dr. S. H. Goodwin, Proctor Academy; and Professor W. W. Henderson, Brigham Young College.

A. O. GARRETT,
Secretary

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

THE 433d regular meeting of the society was held April 20, 1909, President Hough in the chair.

The first part of the evening was devoted to a paper on "The Peoples of the Philippines," by Dr. Daniel Folkmar, formerly lieutenant-governor of the province of Bontoc, and consisted principally in the presentation of the results of anthropometric studies of 800 to 1,000 Filipinos in the prison of Bilbid. While the Negritos and other interior tribes were touched upon, Dr. Folkmar confined himself in the main to the Moros and the eight principal Christian peoples—the Tagalogs, Bisayas, Pampangas, Ilocanos, Pangasinans, Cagayans, Zambals and Bicolis. The investigations seemed to show a division of the Filipinos into two principal types, exclusive of the Negritos, a southern, or perhaps we should rather say coastal, and a northern or interior type, the Moros, curiously enough, occupying an exact intermediate position. At the same time Dr. Folkmar expressed greater confidence in language as a means of classification in the Philippine group than physical characteristics. He considered that, with the exception of the Negritos, all Philippine tribes were affiliated with the Malayan race and constituted part of the Malay problem. In discussing this paper Dr. Boas stated that the anthropological problems of south-eastern Asia were concerned with three races, the Malayan, the Negrito, and a short but light people represented by the Veddahs of Ceylon.

The society then listened to reports of its officers for the past year, and proceeded to the election of officers for 1909 to 1910, which resulted as follows:

President—J. Walter Fewkes.

Vice-president—James Mooney.

Secretary—John R. Swanton.

Treasurer—George C. Maynard.

Additional Members of the Board of Managers

—I. M. Casanowicz, J. N. B. Hewitt, F. W. Hodge, C. H. Robinson, Mrs. M. P. Seaman.

JOHN R. SWANTON,
Secretary

THE AMERICAN CHEMICAL SOCIETY. NEW YORK SECTION

THE seventh regular meeting of the session of 1908-9 was held at the Chemists' Club on April 9. The following papers were presented:

"The Municipal Explosives Commission of New York," by A. A. Breneman.

"Note on the Nitration of Triphenylmethane," by R. Schwartz.

"The Volumetric Determination of Cerium," by F. J. Metzger.

"Does Thorium exist as Silicate in Monazite?" by O. Kress and F. J. Metzger.

"The Reversal of the Photographic Image," by Wilder D. Bancroft.

Owing to the interference of the dates of the American Electrochemical Society meeting and the Congress of Applied Chemistry, there will be but one more meeting this season, to be held May 14.

C. M. JOYCE,
Secretary

THE TORREY BOTANICAL CLUB

THE meeting of April 13 was held at the American Museum of Natural History at 8:30 P.M. and was called to order by Mr. Charles Louis Pollard, who presided in the absence of the president and both vice-presidents.

Mr. Norman Taylor, chairman of the field committee, asked that authority be given him to issue a circular letter requesting the members to vote relative to the continuance of the field meetings. The club voted that this authority be given.

The announced paper of the evening on "Botanizing on the Headwaters of the Saskatchewan and Athabasca Rivers" was then presented by Mr. Stewardson Brown. The lecture was illustrated by lantern slides.

THE PHYSICAL BASIS OF LIFE¹

It is frequently stated that the cell is the unit of life, and this is a convenient form of expression, but its exact truth depends upon the conception that one has of life. The cell may be regarded as the morphological unit of life, but form in and of itself, and as recognized by the eye, is not essential to the manifestations of life. We know no life apart from matter, and matter and energy are the only things that we do know. When matter becomes endowed with life, it does not cease to be matter; it does not lose its inherent properties; it is not released from the laws that determine its structure, its attractions and its motions. In studying the organized cell of living things, whether vegetable or animal, whether bone or brain, it should always be borne in mind that it is material in composition, subject to the fundamental laws that govern matter, and possessed of the properties essential to matter.

The only essential, characteristic and constant difference between living and non-living matter is that within the former there is constant and rhythmic metabolism, while in the latter no such process occurs. The living cell is made up of active, labile molecules and these molecules consist of numerous atoms, and each atom contains a large group of electrons; atoms and electrons are in ceaseless, rhythmic motion, while groups of atoms are being constantly cast out of the molecule and replaced by new groups split off from matter outside the molecule. Metabolism, the one char-

¹ Address of the president before the Association of American Physicians, Washington, May 11, 1909.

acteristic phenomenon of living matter, involves intramolecular change; consequently the molecule, and not the cell, is the unit of life. Matter is endowed with life when it becomes the seat of that form of energy which makes of it a metabolic mechanism. As soon as a molecule becomes the seat of assimilation and excretion it is no longer dead; it lives. As a result of assimilation, it acquires the property of building up its own substance; then polymerization follows and reproduction in its simplest form begins. The one phenomenon always manifested by living matter and never exhibited by non-living matter is metabolism. Verworn says:

Vital motion, metabolism, is a complex motion very strongly characterizing the living organism; it consists in the continued self-decomposition of living substance, the giving off to the outside of the decomposition products, and in return, the taking on from the outside of certain substances which give to the organism the material with which to regenerate itself and grow by the formation of similar groups of atoms, i. e., by polymerization. This is characteristic of all living substance.

Aristotle apparently recognized that metabolism is the one characteristic of living matter, for he said:

Life is the assemblage of the operations of nutrition, growth and destruction.

The Greek philosopher and scientist did not know all that is now known about cells, molecules, atoms and electrons, but we must admit that he had a fairly clear conception of the most essential characteristic of living matter.

Du Bois Raymond said that the matter in crystals and non-living substances is in a condition of indifferent static equilibrium, while that in living bodies manifests a motile equilibrium. Bechterew says that we know of nothing in the inorganic world that contains or consists of motile compounds.

Matter is alive when it feeds and excretes.

Crystals grow, and in a sense they multiply, but their growth is not intramolecular; it is by accretion. The living molecule not only absorbs; it assimilates. It chemically alters what it receives. The atomic groups taken into living molecules enter into new combination. The living molecule is not stable; it is highly labile. Its composition is never constant; it is never in a condition of equilibrium. There is a constant reaction between the living molecule and other molecules. This reaction consists in the absorption and assimilation of certain atomic groups and the casting out of others. Apart from other matter it could not exist.

What is accomplished by this constant interchange of atomic groups between the living molecule and outside matter? It is for the purpose of supplying the living molecule with energy. Allen expresses this fact as follows:

The most prominent and perhaps most fundamental phenomenon of life is what may be described as the *energy traffic*, or the *function of trading in energy*. The chief physical function of living matter seems to consist in absorbing energy, storing it in a higher potential state, and afterwards partially expending it in the kinetic or active form. We find in living matter a peculiar proneness to change its composition under the stimulus of slight changes in the energy-equilibrium between itself and its surroundings, energy being readily absorbed and readily dispersed. The absorption of energy coincides with deoxidation and the building up of large molecules. The building up of these large molecules is always accomplished by slow steps; but when formed, the said molecules are very unstable, irritable or, in modern phrase, *labile*. They may be broken down by degrees in some instances; in others their structure may be so precarious as to collapse on the slightest disturbance.

The lability of such a molecule may be compared to that of a house of cards, which can be taken to pieces card by card, or may collapse at once. But the word lability is applied not only to destructive, but also to constructive instability. The molecules of living substance are prone to constructive as well as destructive changes; but as in the house of cards the constructive changes

are the most gradual; and as the structure grows more complex, construction becomes more difficult, and collapse is more imminent. It should be distinctly understood, however, that it is not the mere size of the molecules that makes them labile, but rather the manner in which they are linked together and the amount of potential energy which is included in the molecule.

It is probable that in the absorption of energy by the living molecule, oxygen is released from combination with carbon or hydrogen, and is attached to nitrogen, while in the liberation of energy the inverse takes place. Nitrogen and phosphorus, sometimes with iron and manganese, seem to be, as it were, the master elements within the living molecule. It is by virtue of their chemism that groups are detached from extracellular matter, taken into the living molecule, and assimilated by an atomic rearrangement; and, furthermore, it is on account of the lability of the compound thus formed that potential energy is converted into kinetic and all work is accomplished.

Life is function and not form, and moreover it is a molecular function. The cell is made up of many and possibly of diverse molecules, but it is the function of the intracellular molecules that determines the nature of its activities. The following quotation from Nussbaum, as given by Loeb, shows that the biologist recognizes that the cell is not the unit of life.

The cell is not the ultimate physiologic unit of life, even though it must remain such for the morphologist. We are, however, not able to tell how far the divisibility of a cell goes, and how we can determine the limit theoretically. Yet, for the present, it will be well not to apply to living matter the conceptions of atoms and molecules which are well defined in physical chemistry. The notion, *Micella*, introduced by Naegeli, might also lead to difficulties, as the properties of living matter are based upon both nuclein and protoplasm. The cell consequently represents a multiple of individuals.

Pflüger has shown that the egg, which has been thought to be a biologic unit, can give rise to many individuals, and Loeb states that his own experiments, as well as those of Driesch, confirm this finding.

In his interesting monograph on the "Biogen Hypothesis," Verworn objects to saying that a molecule lives. He states that this is illogical.

A living thing is only that which demonstrates the phenomenon of life—something that changes itself. A molecule of a given compound, so long as it remains unchanged, can not be said to be living.

Then, in order not to speak of living molecules, he introduces the term "biogen molecule." Surely, this is a distinction without a difference. I agree with the distinguished German physiologist that a molecule of a cell, so long as it remains unchanged, can not be said to be living, but the point is that living molecules do not remain unchanged. When life is latent, as it is in spores, seeds and ova, the molecule can not be said to be alive, neither are the cells alive; but when placed under favorable conditions, the change between atomic groups in the molecule and the extracellular food substance begins, and life manifests itself. A seed contains the germinative cell, a specific ferment and the stored food. The seed is not alive; it possesses only latent life. So long as it remains merely a seed the ferment has no action on the stored food, but place it under suitable conditions of temperature and moisture and the ferment begins to break down the stored protein, and as a result of the chemical cleavage induced by the ferment, relatively simple nitrogenous bodies, such as the mono-amino acids, tyrosin and leucin, and the diamino bodies, arginin and lysin, are formed. These substances begin to react with the molecules within the germinative cell, and latent life is quickened into the active form; the mechanism begins to

work and growth commences. Many of the lower forms of life can not feed upon the proteins. This is true of the yeast cell. These cells grow rapidly when placed in a solution of sugar and nitrates, but proteins must be broken up by putrefactive bacteria before yeast organisms can feed upon them. Indeed, many of the cells in the body of man can not feed upon the complex proteins, which must be split up into simpler groups by the digestive enzymes before the cell molecules can absorb and assimilate them. Even the carbohydrate starch must be hydrated and its elements rearranged as the constituents of a more labile molecule before it can become a source of energy in muscle. Solutions of proteins injected into the blood of man are poisonous, but the same substances, after being properly split up, are valuable sources of energy, and some are essential to the continuance of those functions that constitute life.

The atomic groups cast out from the living molecule are not altogether waste products, for among them are the specific secretions which act upon the extramolecular substance, and fit it for absorption and assimilation. Many of these substances have a reversible action. The colon bacillus will feed at one time on solutions of highly complex proteins, the secretion splitting up the large molecule into smaller groups, thus acting as an analytical agent. The same bacillus will grow in a medium that contains available nitrogen only in the form of amino-acids, its secretion acting as a synthetic agent and building up complex bodies out of simpler ones. It is by means of the specific secretion that the living cell, or the molecules of which it is composed, feeds, or, in other words, breaks up the pabulum placed within its reach into groups suitable for absorption or assimilation. In case of fixed cells the food stuff must be brought to the cell or within close range of

it before it can be prepared for assimilation. Life in a cell molecule ceases when food is withdrawn, or when the secretion is wanting, or from any cause made inactive. No living molecule can continue to function when new material is wanting. Each living, acting molecule has a selective action in the assimilation of new material, and this is quite indicative of metabolism being a chemical or intramolecular process. It might be supposed that a living molecule is a highly complex body, possibly with many basic and many acid groups. In the process of metabolism an acid group is cast out and this enters into one of the molecules of the foodstuff, setting free another acid group which takes the place of the group cast out. In this way the living molecule feeds, regenerates itself, and supplies itself not only with new matter but with energy. These movements are rhythmical and continue in the same tempo so long as conditions remain the same. It may be that groups of different sizes are cast out and replaced from time to time, smaller groups being thrown off more, and larger ones less, frequently. We have reason for believing that in many living molecules there are at least two kinds of metabolism which occur simultaneously, but in different tempo. The more frequent consists in casting out from the living molecule relatively small groups consisting largely of oxidation forms of carbon and hydrogen. The less frequent is a nitrogenous metabolism in which urea or some antecedent of this substance is eliminated and is replaced by fresh material. It is possible that individual molecules are broken up beyond repair in the nitrogenous metabolism, the worn-out one having already reproduced its successor by polymerization. The tempo with which these processes of metabolism occur may be altered by changing the external conditions. When the speed is too

great or when it is too slow continued metabolism, or life, may be endangered. The tempo is altered when it becomes necessary for the living matter to do work. More energy must be absorbed, the greater the work done, and this needed increase in energy can be secured only by increasing the speed with which the metabolic process takes place.

I wish to call attention to the fact that in even the simplest unicellular organism its normal processes are purposeful. The cell molecules attract substances that serve them best as foods. From these they select the parts that they can utilize, and reject the parts that can not serve them. This is true, however, only within certain limits, because often they do absorb substances that lead to their own destruction. Their selection seems to be guided by chemism, which on the whole leads them in the safe way, but may cause their destruction.

It is not my purpose to discuss at this time the question of the relation between the existence of a nervous system and conscious action or psychical activity, but I do wish to call attention to the fact that low forms of life in which there is no trace of nerve tissue behave in a purposeful manner. Many of the low forms of life in which there is no trace of the development of the sense of sight, or sound or feeling, are responsive to light, to sound and to stimulation. We see most convincing evidence of this in the phenomena of helio-, thermo-, chemio- and galvano-tropism. Under the influence of optical, thermic, chemic and electric stimuli these low forms of life, devoid of any trace of nervous system, manifest movements that serve them in self-protection, in securing food and in reproduction. These lower forms of life without nerve tissue apparently learn by experience to choose between what is good and what is bad for them. Metelnikov

placed carmin in a fluid in which ciliated infusoria were swimming. At first they absorbed the carmin granules, but having done so once, they could not be induced to try this food again. This behavior, it must be admitted, is much the same as that of the dog which, having been struck with a stick once, runs away when he again meets the same man with a stick. Certain infusoria that feed upon bacteria select the species upon which they feed. The movements of infusoria in pursuit of their prey are certainly purposeful, if not conscious. The readiness with which low forms of life accommodate themselves to altered environment shows that they are capable of being trained or educated to a certain extent. Stahl has shown that a certain plasmodium flees when sprinkled with salt, but if the salt be added to the medium gradually the organism accommodates itself to the new medium. Purposeful action is manifested by plants as well as by animals, and by both unicellular and multicellular plants. This is in evidence in the movements of algæ and moulds. Leaves turn toward the sources of light and heat, and the roots seek nourishment in the earth. The capability of responding to certain stimuli is common to all cell life, whether it be vegetable or animal.

In multicellular animals, such as man, we have colonies, or groups of cells, or organs, bound together. Each kind of cell has its own peculiar molecular composition and through these living molecules the work of the organ is accomplished. A framework of bone, cartilage and connective tissue support and hold in position these organs. They are supplied with food material by a common system of blood and lymph vessels, and their harmonious action is secured through the nervous system. The digestive organs roughly prepare the food for all, but each has its own secretion

which shapes the pabulum for intramolecular assimilation. This is accomplished in both instances by means of specific ferments that are formed within the cell molecules. These enzymes bring about changes in the pabulum at the relatively low temperature of the body which can be wrought by inorganic chemicals only at much higher temperature and after prolonged action.

The cell molecules in each organ of the higher animals have their own peculiar composition and manifest their own peculiar function. The chemical composition of the liver differs from that of every other organ in the body. The liver cell molecules cast out their own characteristic products and absorb and assimilate special atomic groups. Moreover, the tempo of metabolism probably differs in each organ, or at least the cell molecules of each organ have their own optimum tempo to which their metabolic processes conform. The more complicated the structure of the cell molecule, the more energy may be stored in it, the greater its lability and the greater is its susceptibility to altered conditions. In the nervous system the molecular structure is the most complex, the amount of stored energy is at the maximum, and the readiness with which this energy may be released is most manifest. In the active central nervous system, or the brain, we have the highest manifestation of the molecular functions that characterize life. The molecules that make up this structure are most susceptible to alteration in conditions. In their function they are influenced by slight disturbances in other organs. We have heard much of late concerning the influence of mind upon the body, and many who speak upon this subject seem to assume that there is some entity, called mind, that controls the body to which it is superior, and apart from which it may exist. This dualistic doctrine is as old as the philosophy

of Plato; it always has been and remains to-day a dogma without scientific support, and as a hypothesis it has led to the discovery of no scientific fact. Every attempt to apply it to the treatment of disease has led to the development of conscious or unconscious charlatanism, and has resulted in more or less marked atavism. The term functional disease is now being used by those who know but little concerning the functions of the body in either normal or abnormal states. It seems to be inferred or assumed by those using this expression that a mysterious power has been given to some to set the mechanism of the disordered body aright, although those supposed to be possessed of this gift have no knowledge of, or but imperfect and superficial acquaintance with, the functions of the various organs and their interrelations. In truth we have no evidence of the existence of a functional disease as thus understood. In health the several organs of the body function harmoniously; in disease there is lack of perfect harmony, and we know of no disease in which this condition does not exist. We may not always be able to find where the basic fault lies, but shall we for this reason stop looking for it, shut our eyes, give over our search and ask some individual, quite ignorant of the body and its functions, to undertake the task of inducing harmonious activities? Of mind apart from the body we know nothing. Of the brain as one of the correlated organs we know something, and by continued and patient research we hope to learn much more. We do know that the cell molecules of the brain are the most complex, the most highly labile and the most susceptible to external influences of any of the structures that constitute that community of organs which makes up the individual. We know that the introduction of such poisons as alcohol, morphine and cannabis indica

into the blood, leads to disorder of cerebral function; that failure to function properly on the part of the liver, kidney, spleen or other organ, modifies the activity of the brain; and that, on the other hand, altered function in the brain may disturb the functions of these other organs. The medical profession is fully aware of the fact that man thinks not only with his brain, but in a certain sense with every organ in his body. In other words, we know that the perfection of activity of the brain is modified and determined by the proper and healthy activity of other organs of the body, although we are ready to admit that our knowledge along this line is by no means complete. We have studied in myxedema the effect of disordered function in the thyroid upon the central activity. We have learned that in chronic malaria, the central activities, the ideals and the philosophy not only of the individual but of nations, may be debased; that in uncinariasis and other forms of parasitism like results may follow. In short, medical observation and study have shown that healthy cerebral function is to be found only when the activity of the brain is properly influenced by normal function of all the correlated organs. We know equally well the influence of the brain on the other organs of the body. We are fully aware of the fact that impulses may be started in the brain through any of the five senses that may favorably or unfavorably influence the activities of correlated organs, and for centuries the medical profession has employed this physiological principle in the treatment of disease. Savory dishes, pleasingly garnished, through the sense of sight and smell tempt the appetite and stimulate the flow of the digestive juices. Cheerful surroundings aid digestion. Cheering words improve the circulation, and hope is often the best tonic that the physician can

administer. As I have stated, the medical profession has understood and has utilized these physiological facts for centuries, and there is nothing in them to justify the founding of any new cult. That the brain of one individual may be modified in its activity by the sounds that fall from the lips of another is as much of a physical fact as that of the contraction of a muscle by the passing of an electric current through its nerve. There is nothing in this to justify a dualistic doctrine involving the existence of mind apart from and superior to matter. Indeed, every step in the process is in accord with the laws of physics and chemistry. The vocal organs of the speaker set in motion the sound waves that strike upon the ear of the hearer, the auditory nerves carry the impulse to the brain center, and the brain molecules respond. There is nothing in it that the most materialistic of philosophers might not endorse. Sensibility, or the capability of responding to stimuli, is, as Claude Bernard said, to a certain extent the starting-point of life; it is a primary phenomenon and from it all others, physiological, intellectual and moral, develop. Bechterew holds that irritability or sensibility is due to a motile cohesion in the biomolecule, and that psychical activity is the result of a complex function of this molecule. Since nothing comes from nothing, the basis of psychical action must lie in the physico-chemical elements of the organism.

UNIVERSITY OF MICHIGAN

*ETHNOLOGICAL EVIDENCE THAT THE
CALIFORNIA CAVE SKELETONS ARE
NOT RECENT*

SINCE the discovery of the celebrated Calaveras skull, many human skulls and skeletons have been found in caves along the west slope of the middle Sierra.¹ The presence of human

¹See Sinclair, *Univ. Calif. Pubs., Am. Arch. and Eth.*, Vol. 7, No. 2, 1908.

remains in these caves has been interpreted to mean that the Indians now living in the region practise cave burial, or did practise it until recent times. This is an error. The Indians of this region, the Mewuk, burned their dead, and never under any circumstances put them in caves. These Indians believe the caves to be inhabited by a stone giant, whom they call Chehalumche, who sallies forth at night in search of food. He preys, by preference, on people, but when he can not get people, takes deer or other animals. He never eats his victims in the open but carries them into the caves and there devours them. Members of several subtribes of the Mewuk have told me this, and have looked with horror on the suggestion that they or their ancestors might ever have put their dead in caves. They say: "Would you put your mother, or your wife, or your child, or any one you love, in a cave to be eaten by a horrible giant?" The idea is so abhorrent to them that the theory of cave burial must be abandoned as preposterous. The Mewuk feel that the finding of human bones in these caves must convince us of the truth of their belief in the occupancy of the caves by Chehalumche, the bones being those of the victims he has carried there.

The mythology of the Mewuk does not admit of any migration but describes the creation of the people in the area they still inhabit. This, in connection with the fact that these Indians speak a language wholly different from any known in any other part of the world, proves that the Mewuk have occupied the lands they now occupy for a very long period—a period which in my judgment should be measured by thousands of years.

This argues a great antiquity for the cave remains, for they must be those of a people who inhabited the region before the Mewuk came—and this takes us back a very long way into the past.

C. HART MERRIAM

FRU SIGNE RINK

We regret to announce the death, April 19, in Kristiania, Norway, of Fru Signe Rink, widow of the late H. Rink, formerly Danish governor of Greenland and supervisor of the

Greenland commerce; and known all over the world for his valuable contributions to the ethnology of the natives of Greenland and the Eskimo people generally. Fru Rink survived her husband many years, and was the author of several little books and other writings on the tales, home life and traditions of a people with whom she had a partial connection by blood. Probably no one in Europe had a more intimate knowledge of their character, though it was with difficulty she could be persuaded to the publicity of authorship. Personally she was of a most kindly, hospitable and vivacious disposition, and her death will leave sorrow in many hearts. A daughter resident in Kristiania survives her.

W. H. DALL

EXHIBIT OF THE BUREAU OF EDUCATION AT THE ALASKA-YUKON-PACIFIC EXPOSITION

THE plans of the National Bureau of Education for an exhibit at the Alaska-Yukon Exposition have been formed with special reference to the interests of teachers and officers of education.

In the section assigned to the bureau in the government building, a conference room has been fitted up where visiting educators will find ready welcome. Here they may consult publications pertaining to current movements in education, and a select reference library for teachers. The classified catalogue of this library will be furnished upon request. Arrangements for professional conferences in this room at stated hours may be made if desired.

The space surrounding the conference room is given up to exhibits pertaining to movements for the uplift and extension of rural education. These exhibits illustrate what is actually being done for the improvement of rural schools in the more progressive communities, and thus by concrete examples suggest the means of meeting needs which are felt in every part of the country. The separate exhibits have been prepared under the direction of a committee of the bureau appointed by the Commissioner of Education, assisted by expert collaborators in different sections of the country.

Special interest attaches to exhibits presenting typical courses of instruction in art, in nature study and in geography, prepared by authorities in these respective branches who are also masters of the art of graphic presentation.

Manual training, as carried out in the rural high schools, which are rapidly increasing in number, is well represented in the section. The importance of this training is emphasized by a typical course of manual training exercises equally adapted to city and country high schools, arranged for this occasion by Dr. Calvin M. Woodward.

The absorbing interest in this country at the present time in the development of high schools in which provision is made for agriculture, domestic science and manual arts, is emphasized in the exhibit by material pertaining to these subjects as parts of the school curriculum. This material consists of monographs, leaflets and photographs by means of which every phase of this comparatively recent departure in our educational provision is illustrated.

The equipment of rural schools is vastly increased by traveling and loan museums of which important examples have been supplied to this exhibit from the National Department of Agriculture, and from the chief scientific museums of the country which are rapidly coming into the same relation with the common schools as the traveling libraries.

The entire exhibit is arranged around two centers, as it were, namely, the model of an improved type of rural school, and a graphic presentation of the consolidated rural school. This plan emphasizes the fact that the first condition of improvement in common schools is their suitable housing.

The different collections in the exhibit are all fully labeled, and credit is given in each case to the source from which the particular exhibit was derived.

It is hoped that all teachers and school officers visiting the exposition will avail themselves of the opportunity thus afforded by the National Bureau for the study of salient educational problems of the hour, and also for professional meetings and conferences.

Special appointments for the conference room, and documents intended for circulation may be secured by addressing Mr. James C. Boykin, acting representative of the Interior Department at the Alaska-Yukon Exposition.

DELEGATES TO THE DARWIN CELEBRATION AT CAMBRIDGE

THE following is the list of American institutions which have been invited to send delegates to the celebration to be held in Cambridge next month in honor of the Darwin centenary and of the delegates who have been appointed:

- Ann Arbor, University of Michigan, Dr. H. S. Carhart.
- Baltimore, Johns Hopkins University, Dr. J. M. Baldwin.
- Berkeley, University of California, Dr. Jacques Loeb.
- Boston, *American Academy of Arts and Sciences, Professor W. Gibson Farlow.
- *Boston Society of Natural History, Professor C. S. Minot.
- Cambridge, Harvard University, Dr. A. Agassiz and Dr. Theobald Smith.
- Charlottesville, University of Virginia,
- Chicago, University of Chicago, Professor J. M. Coulter.
- Evanston, Northwestern University,
- Cold Spring Harbor, Station for Experimental Evolution, Dr. C. B. Davenport.
- Columbus, Ohio State University,
- Indiana, *Franklin Literary Society,
- Ithaca, Cornell University, President J. G. Schurman.
- Madison, University of Wisconsin, Dr. F. B. Powers.
- Minneapolis, University of Minnesota, Professor E. van Dyke Robinson.
- New Haven, Yale University, Professor R. H. Chittenden.
- Connecticut Academy of Arts and Sciences, Professor Tracey Peck.
- Peabody Museum of Natural History, Professor R. H. Chittenden.
- New York, Columbia University, Dr. E. B. Wilson.
- New York University, Dr. H. M. Biggs.
- *New York Academy of Sciences, President C. F. Cox.
- American Museum of Natural History, Director H. C. Bumpus.

Palo Alto, Stanford University, Professor V. L. Kellogg.

Philadelphia, University of Pennsylvania, Dr. C. C. Harrison.

*Academy of Natural Sciences, Dr. A. E. Brown.

*American Philosophical Society, Professor H. F. Osborn.

Pittsburg, Carnegie Institute, Dr. Samuel Harden Church.

Princeton, Princeton University, Professor W. B. Scott and Professor W. O. Richardson.

San Francisco, *California Academy of Sciences, Dr. G. E. Hale.

St. Louis, Washington University,

Washington, Smithsonian Institution, Dr. C. D. Walcott.

Carnegie Institution, Dr. R. S. Woodward.

Academy of Sciences, Dr. L. O. Howard.

U. S. Geological Survey,

The George Washington University,

Department of Agriculture,

Woods Hole, Marine Biological Laboratory, Dr. E. B. Willson.

*Societies of which Charles Darwin was an honorary member.

AMERICAN CHEMICAL SOCIETY

THE summer meeting of the American Chemical Society will be held in Detroit, Mich., June 29 to July 2, and there is every prospect that the meeting will be one of the most largely attended and successful in the society's history. The local society of Detroit chemists is putting forth every effort to insure a successful gathering. One day of the meeting will be spent in Ann Arbor as the guests of the University of Michigan.

The council of the society will meet on June 28 and the opening session of the general meeting will be on the morning of June 29 in the Central High School which offers every facility for the meeting of the various divisions and sections of the society.

The Hotel Pontchartrain has been selected as headquarters for the meeting.

Titles of papers to be read at the summer meeting should be sent to the secretary of the society or to the secretaries of divisions and to find place on the program should reach me on or before June 7. Papers for the section of chemical education should be sent to the chairman, H. P. Talbot, Institute of Technology, Boston, Mass., before June 5.

A full program of the meeting will be sent to all members of the society about June 20.

CHARLES L. PARSONS,
Secretary

DURHAM, N. H.

SCIENTIFIC NOTES AND NEWS

At the last meeting of the American Academy of Arts and Sciences, it was voted to award the Rumford premium to Professor Robert W. Wood, of the Johns Hopkins University, for his discoveries in light and particularly for his researches on the optical properties of sodium and other metallic vapors.

At the last meeting of the Rumford committee of the American Academy the following grants were made: To Professor M. A. Rosanoff, of Clark University, for his research on the fractional distillation of binary mixtures, \$300; to Professor C. E. Mendenhall, of the University of Wisconsin, for his research on the free expansion of gases, \$300.

PROFESSOR F. W. PUTNAM has been elected honorary member of the Societa Italiana d'Anthropologia, Ethnologia e Psicologia Comparata of Florence, Italy. Since 1887 he has been a corresponding member of this society.

DALHOUSIE UNIVERSITY has given its doctorate of laws to Dr. A. Ross Hill, president of the University of Missouri, who graduated from Dalhousie in 1892.

PROFESSOR R. MELDOLA, F.R.S., has been elected a member of the Athenæum Club for scientific eminence.

THE Marine Biological Station of San Diego having developed to such an extent as to require the entire time of the scientific director; and having been so endowed as to make it possible for him to devote himself to it, the present director, Professor Wm. E. Ritter, will relinquish the active headship of the department of zoology in the University of California at the close of the present academic year and will take up his permanent residence at the station. After June 1 his address will be, therefore, La Jolla, California.

DR. E. E. SOUTHARD has been appointed pathologist to the Massachusetts Board of Insanity, from May 1, 1909. The position is a new one in Massachusetts. The appointee will be required "to visit the different institutions from time to time as the representative of the board, with particular reference to the supervision of clinical, pathological and research work, and, so far as possible, in an advisory capacity, to stimulate interest, co-ordinate efforts and promote the best results in this direction."

PROFESSOR E. T. ROBBINS, assistant animal husbandman, Iowa Experiment Station, has accepted a position on the editorial staff of the *Breeders' Gazette*, Chicago, Ill.

A GEODETIC survey department for Canada has been established under Dr. W. F. King, chief astronomer of the dominion.

DR. HEINRICH RIES, professor of economic geology at Cornell University, has been commissioned by the Canadian government to make a survey of the clay deposits of Canada.

THE University of Pennsylvania has granted leave of absence until October 1, 1910, to Philip P. Calvert, Ph.D., assistant professor of zoology, to enable him to go to Central America to pursue further researches on the ecology of tropical Odonata. This is in continuation of the studies which have grown out of his preparation of the account of these insects for the *Biologia Centrali-Americana*. Dr. and Mrs. Calvert sailed from New York on April 17 for Costa Rico.

DR. CARL LUMHOLTZ has gone to the arid regions of Sonora and the upper part of Lower California to make ethnological research among the Pima, Papago and Cocopa Indians. He will also study the physical geography of the little-known region between Rio de Altar and the mouth of the Colorado River. Dr. Lumholtz will be gone until next winter, returning in February or March.

DR. RAYMOND F. BACON, of the chemical division of the Bureau of Science, Manila, is spending five months in this country.

PROFESSOR VON RUNKER, director of the Agricultural Institute of Breslau, Germany, and Professor Erich Tschermak-deer von Sey-

senegg, of the College of Agriculture, Vienna, Austria, have been sent by their governments to study agricultural experiment stations in the United States.

PROFESSOR CHARLES BASKERVILLE, director of the chemical laboratory, College of the City of New York, sailed for London on May 15 on the steamer *Kroonland*, to attend the Seventh International Congress of Applied Chemistry. He will be abroad all summer.

DR. MAX MEYER, professor of experimental psychology in the University of Missouri, will leave toward the end of May for a year's stay in Europe on leave of absence.

DR. A. LAWRENCE LOWELL, president-elect of Harvard University, will give the Phi Beta Kappa address at Columbia University on June 1, at 4:30 in the afternoon. The subject will be "Competition in College."

PROFESSOR RAYMOND DODGE gave an illustrated lecture on "The Nature and Practical Importance of Fatigue," before the Middletown Scientific Association on May 11.

PROFESSOR ROBERT FLETCHER, of the Thayer School of Civil Engineering at Dartmouth College, will give the memorial address at the Rose Polytechnic Institute of Terre Haute, Ind., on June 8. The occasion is the graduation of the twenty-fifth class, and the commemoration of founders day.

PROFESSOR JOHN C. OSTROP, of Stevens Institute of Technology, delivered an address before the Canadian Society of Civil Engineers at Montreal, Canada, on the evening of May 6. The subject was "Some Features of the Design and the Construction of the Manhattan Suspension Bridge." The address was illustrated with lantern slides and brought out a spirited and interesting discussion.

AN anonymous benefactor has expressed his willingness to contribute a sum of £500, or so much of this sum as may be required, to supplement the £500 which the senate has voted towards defraying the cost of the Darwin commemoration at Cambridge.

DR. F. G. YEO, F.R.S., emeritus professor of physiology in King's College, London, has died at sixty-four years of age.

THE late Mr. W. H. Hudleston, the eminent geologist, has left his unrivaled collection of types of Oolitic Gasteropoda to the Sedgwick Museum, Cambridge, and £1,000 to the Geological Society.

THE University of Colorado has received an interesting collection of fishes from the river Nile, presented by the Egyptian government through Dr. Boulenger, of the British Museum.

WE learn from *Nature* that at a special general meeting of the Zoological Society on April 29, it was decided to dispose of the site of the society's freehold premises in Hanover Square, and to expend the proceeds upon the erection of new offices, library and meeting-room at the Zoological Gardens in Regent's Park, and on the general improvement of the gardens.

It is expected that the Marine Laboratory of the Johns Hopkins University will be reopened in Jamaica in 1910, so that graduate students and instructors will have the opportunity to study marine and mountain flora and fauna in the tropics and to obtain material for research problems.

On May 8 the Theta Chapter of Alpha Chi Sigma, the national chemical fraternity, was installed at the University of Nebraska by Dr. J. H. Mathews, of the University of Wisconsin, and Mr. L. S. Palmer, of the University of Missouri. The following men constitute the new chapter: Professor Benton Dales (director), Professor George Borrowman, Jr., P. B. Barker, O. L. Barneby, H. J. Broderson, M. R. Daughters, C. J. Frankforter, R. L. George, L. F. Gieseke, W. L. Hadlock, F. C. Hawks, W. D. Jensen, S. A. Mahood, G. R. McDole, W. H. Warren, A. L. Weaver and E. F. Wilson. Alpha Chi Sigma is a professional chemical fraternity, organized in 1902, with the purpose of promoting a fraternal spirit among chemists, of providing a reward for faithful undergraduate work and of providing a closer relationship between alumni and students. It now has chapters at the University of Wisconsin, University of Minnesota, Case School of Applied Science, University of Missouri, University of Indiana,

University of Illinois, University of Colorado and University of Nebraska. A chapter will shortly be installed at the Rose Polytechnic Institute.

THE annual dinner of the Syracuse Chapter of Sigma Xi was held at the St. Cloud Hotel on May 13. Research reports were called for as follows: department of astronomy, Professor H. A. Peck; chemistry, Professor E. N. Potter, zoology, Professor C. H. Richardson; mathematics, Professor W. H. Metzler; botany, Professor W. L. Bray. Professor E. N. Pattee was elected president; Dr. H. D. Senior, vice-president; Professor C. H. Richardson, secretary, and Professor F. F. Decker, treasurer. Mr. E. C. Keenan and Mr. N. E. Loomis were elected to membership as graduate students.

THE fourth meeting of the Research Workers in Experimental Biology of Washington was held at the Medical School of George Washington University on May 1. Dr. Oswald Schreiner, of the Bureau of Soils, spoke on "Some Factors of Soil Fertility." The lecturer laid special emphasis upon the influence of organic matter of the soil with reference to the biochemical relationships which exist between soil and crop and the microorganisms within the soil. The influence of organic compounds isolated from the soil on plant growth was illustrated by lantern slides and photo-micrographs of the crystalline materials were also shown. The lecture was followed by discussion.

MR. HENRY P. PHIPPS was formally presented on May 12 with the gold medal awarded him by the International Anti-Tuberculosis Association for his aid in waging war against consumption. The presentation was made by Dr. Lawrence F. Flick, at a dinner tendered at the Bellevue-Stratford in Philadelphia. Mayor Reyburn presided and the speakers were introduced by former Ambassador Tower. Mr. R. W. DeForest, president of the New York Charity Organization Society, responded to the toast "Henry Phipps, Citizen of New York," Hon. H. D. Harlan, chief judge of the supreme bench, spoke on "Henry Phipps, benefactor, of Baltimore." Dr. William J.

Holland, director of the Carnegie Museum, spoke on behalf of Pittsburgh and Dr. Talcott Williams, on "Henry Phipps, a native of Philadelphia."

LORD AVEBURY took the chair at the annual *conversazione* of the Selborne Society on May 7. Two lectures were given, the first on "How Birds Fly," by Mr. F. W. Headley, F.Z.S., science master at Haileybury College, and the second on "How Men Fly," by Mr. T. W. K. Clarke, A.M.I.C.E., the first engineer to build aeroplanes in Great Britain. Mr. James Buckland exhibited a number of lantern slides illustrating the birds that are in danger of extermination in various parts of the world. There was also a display of microscopes and natural history exhibits.

THE seventy-seventh annual meeting of the British Medical Association will be held in Belfast on July 28-31. The president-elect is Sir William Whitla, professor of materia medica and therapeutics, Queen's College, Belfast. The address in medicine will be delivered by Dr. R. W. Philip, that in surgery by Professor A. E. J. Barker, and that in obstetrics by Sir John W. Byers. The popular lecture will be delivered by Dr. J. A. Macdonald.

News has been received from Dr. Charcot's Antarctic expedition which has arrived at Deception Island, one of the South Shetland group, on December 22. The *Pourquoi-Pas* left the island on Christmas day for Port Lockroy, from which it was to proceed to the south. Dr. Charcot hopes to establish his winter quarters on Alexander Land, the name given to the region lying to the south of Graham Land in about 70° south latitude, which will form a point of departure either for exploring the coast line towards King Edward VII. Land or for penetrating into the interior. No further news may be expected from Dr. Charcot for at least a year.

A NATIONAL conference on criminal law and criminology in celebration of the fiftieth anniversary of the founding of the Northwestern University School of Law will be held in the Northwestern University building, Chicago, on June 7 and 8.

THE annual meeting of the Naples Table Association for Promoting Scientific Research by Women was held on April 24 by invitation of Director Bumpus, at the American Museum of Natural History. Miss Caroline McGill, of the University of Missouri, was appointed a scholar of the association at the Naples Station. The award of the prize of one thousand dollars offered every second year for the best thesis written by a woman on a scientific subject, embodying new observations and new conclusions based on an independent laboratory research in biological, chemical or physical science, was made to Miss Florence Buchanan, D.Sc., of London University, fellow of University College, London, for a thesis entitled "The Time taken in the Transmission of Reflex Impulses in the Spinal Cord of the Frog." Of the eleven theses presented in competition five were sent from England and one from Canada. The subjects of four were morphological, of two bacteriological, of two zoological, one physiological, one was in parasitology and one in physical chemistry.

THE seventh Congress of the International Institute of Sociology will meet in Bern, from July 20 to 24 next at the invitation of the Swiss government. The sessions will be held in the university and under its auspices. Senator Baron R. Garofale, of Venice, will preside, and the subject of social solidarity will be discussed from a variety of wholly scientific points of view. Representatives of many countries, including the United States, will be in attendance. It will be remembered that the last congress was held in July, 1906, at the University of London, under the presidency of the eminent French economist, M. Levasseur, when the opposite question of social struggles was exhaustively canvassed.

THE International Congress of Psychology will hold its sixth meeting in Geneva this year from August 3-7, under the Presidency of Professor Thomas Flournoy. The program, as noted in the *British Medical Journal*, includes discussion of general and special topics, questions of standardization, demon-

stration of apparatus, and individual papers. The general topics to be discussed are feelings (by Külpe and Sollier), subconsciousness (Dessoir, Janet, Prince), measure of attention (Patrizi, Ziehen), religious psychology (Höfding, Leuba). The special topics are the psychopedagogical classification of backward pupils (Decroly, Ferrari, Heller, Witmer), pedagogical psychology (Ioteyko), orientation at a distance (Thauziès), perception of position and movement of the body and limbs (Bourdon). Under standardization will be included terminology, standard colors, enumeration of errors in testimony experiments, notation of age of children, mathematical determination of numerical results of experiments. Communications relative to the congress should be addressed to the general secretary, Professor Ed. Claparède, 11, Avenue de Champel, Geneva.

THE skeleton of the fine male *okapi* presented to the Natural History Museum some time since by Major Powell-Cotton has, we learn from the *London Times*, been articulated and put out in the east corridor. The attitude corresponds with that of the mounted skin, for which the museum is indebted to the same donor, the head and neck being nearly in a line with the back. When the *okapi* was described it was believed that the neck was partly raised, and this idea was embodied in mounting the skin of the female presented by Sir H. H. Johnston. It has since been found that the head and neck are stretched forwards. In addition to the two mounted specimens mentioned, the museum has a third, obtained by the Alexander-Gosling expedition, and presented by Mr. Boyd Alexander. This possesses the small bare tips to the horns, which are not developed in Major Powell-Cotton's specimen. In one of the cases of the geological gallery casts of the skull of the *okapi* have been put out by the side of the skull of the extinct *Samotherium*, its nearest ally, for comparison. So close is the resemblance between these two forms that in the official guide to the extinct mammals and birds one species of *Samotherium* is referred to as "an extinct *okapi*."

UNIVERSITY AND EDUCATIONAL NEWS

THE recent New York legislature passed the bill providing that the governor of the state shall appoint five members of the board of trustees of Cornell University. The bill to establish at Cornell a state school of sanitary science and public health was not passed. For the general support of the State College of Agriculture, Cornell University, the legislature has appropriated \$175,000, an increase over last year of \$25,000.

PROFESSOR WILLIAM NICHOL, of Kingston, has given to Queen's University, Kingston, Ont., a building for mining and metallurgy, and the Ontario government has appropriated \$100,000 for a chemistry building.

At the recent McGill University convocation it was announced that \$60,000 had been guaranteed by the committee, which intends to establish a chair in memory of the late Dr. Harrington, professor of chemistry. About \$20,000 has already been subscribed and a committee of four has agreed to be responsible for the remaining \$40,000.

THE Sanders chemical laboratory at Vassar College was dedicated on May 15, when brief addresses were made by the donor, Dr. Henry M. Sanders, of New York; President Taylor, and Professor Charles W. Moulton, head of the department of chemistry.

DR. BOYD H. BOBE, assistant professor of philosophy in the University of Wisconsin, has been appointed professor of philosophy in the University of Illinois.

At Williams College, Dr. F. L. Griffin has been appointed assistant Professor of mathematics; Dr. Brainerd Mears, instructor in chemistry and Dr. J. M. Warbeke, instructor in philosophy.

MR. J. K. ROBERTSON, of Toronto University, has been appointed lecturer in physics at Queens University.

MR. WALTER K. VAN HAAGEN, B.S., assistant in chemistry, Lehigh University, has been elected associate professor of chemistry in the University of Georgia.

PROFESSOR ERNST LECHER, of Prague, has been called to the chair of experimental physics in Vienna.

DISCUSSION AND CORRESPONDENCE

GENERA WITHOUT SPECIES

IN response to the suggestion made in SCIENCE of February 26, p. 340, I have received a number of communications, in substance as follows:

I agree throughout with your opinions as expressed in SCIENCE for February 26; . . . I hold a genus is not established unless a type species is named.—J. C. Arthur, Purdue University. (Fungi.)

I entirely agree with you that generic names published without any mention of included species are to be regarded as invalid. It seems to me that a genus can not possibly be constituted without reference to a species.—C. J. S. Bethune, Ontario Agricultural College. (Entomology.)

1. A genus is an aggregation of one or more species. The type of a genus is, must be, an included species, that is, an originally included one. Therefore if there are no species at all how is it possible to have a genus? Genera without species are certainly *nomina nuda*.

2. The author of a genus or species is he who first gives it valid standing. A genus without species is a *nomen nudum* and thus without valid standing. Therefore the first writer to give it validity is the author and its date is that at which this validating is done. It would be absurd in my estimation to do otherwise as in such case we might have some good genus invalidated through preoccupation by a *nomen nudum*.—A. N. Caudell, U. S. National Museum. (Orthoptera.)

Mr. Caudell adds that Messrs. Dyar (Lepidoptera, etc.), Knab (Diptera) and Busck (Lepidoptera), of the National Museum, agree with the above statement.

Genera without included species "are *nomina nuda*."—A. A. Girault, University of Illinois. (Hymenoptera.)

I fully agree with you that the rule of the code quoted by Mr. Coquillett merely means that the genus name itself must be uninominal, and has no bearing on the question under discussion. A genus name without a type species is, I think, untenable; but if it be stated that the genus is founded on an undescribed species, then it might stand as you suggest.—Chas. A. Hart, Ills. State Lab. of Natural History. (Entomology.)

I saw your article in SCIENCE yesterday, and was much interested in it. There are several cases in botany where it seems to me a strict sticking to the letter of the law is a little awkward. Are we to write *Bossekia* Neck. or *Rubacer* Rydb.? It seems to me that Greene has proved that they are the same, yet Rydberg published combinations in *Rubacer* before Greene published them in *Bossekia*.

Mohrodendron and *Carlomohria* are in the same category. Everybody knows what Greene referred to when he published the name, yet he did not make any combinations at that time, and Britton did. If we follow the law exactly in such cases, we are departing somewhat from priority, and it does not seem altogether right to me.—A. A. Heller, Nevada Agric. Exper. Sta. (Flowering Plants.)

On question of validity of generic names when proposed without reference to published description of included species or in connection with such description, please record my vote in the negative.—A. W. Morrill, U. S. Bureau of Entomology.

A genus name can stand only when meeting requirements of binary names, it being recognized that a genus is a group of one or more species.—E. L. Morris, Museum of Brooklyn Institute. (Botany.)

I do not think a generic name should be recognized unless connected definitely with a binomial species. This is in accord with the American Botanical Code and is essential in order to provide types and definitely fix genera.—C. L. Shear, U. S. Dept. Agriculture. (Botany.)

It is probable that generic names published without reference to included species would be rejected by the majority of American zoologists and botanists, though at least some eminent authorities favor their recognition. Probably a more precise estimate of current opinion could be gained by sending out voting papers to all the more active or eminent workers. I venture to suggest that such a plan might be taken up by the American Association for the Advancement of Science. It would not be held or suggested that the votes thus obtained on controversial matters had any legislative significance; but they would undoubtedly have their influence in moulding opinion, while the invitation to vote would in many cases stimulate thought. It seems to me that in the publication of the results of any vote, the names should always be given,

unless the number is very large. In the latter event, representative opinions, with names, could be published.

Whether a plan of this sort could be extended to include the scientific workers of the world (or such of them as might be concerned with the particular matter under discussion) is a difficult question. Efforts of various kinds are being made at the present time to bring the scientific men of the world into closer touch with one another, and it is perhaps not quixotic to suppose that eventually they will be at least as ready and as competent to act together as are those of America at the present time.

T. D. A. COCKERELL

UNIVERSITY OF COLORADO,

March 28

THE FUTURE OF NOMENCLATURE

PROFESSOR T. D. A. COCKERELL's discussion under the heading "Genera without Species" recently published in *SCIENCE*,¹ is of great pertinency at the present time.

Without discussing the question concerning the validity or non-validity of genera described without species named in connection with them, or genera proposed with undescribed types, a question familiar to every systematist, and one which I hope to see discussed by others more competent and learned than myself, I desire merely to make one or two general observations concerning nomenclature as a whole, its function and its future.

Before doing this, however, some remarks concerning the cases considered by Professor Cockerell may not be out of place or without some use.

In the first class of cases, a genus described in the past without a species named in connection with it, I consider as being non-existent—a *nomen nudum*—and it remains such unless subsequently its author or some other refers to it a properly described type species. The genus being non-existent, its name does not have to be recognized again as being that of a zoological unit, excepting as a matter of wisdom; if used again, it has no status unless used as a name based on some definite type

species designated subsequent to its original description, and in such cases the original author of the name should be held responsible for it, mainly as a matter of clearness. I agree with Professor Cockerell's interpretation of the code in cases of this kind. Whether or not these *nomina nuda* made in the past should be used again depends largely on circumstances, and is almost a matter of individual judgment. I think they should be used in most cases to prevent questions of obscure homonymy, and confusion arising from other sources. These remarks bring me to the point I had in mind in regard to this class of cases. I have referred to them as occurring in the past. Should they be allowed to occur in the future? There is no excuse at the present time for cases of the kind being made, but some provision should assuredly be made in the code to prevent them. The code should state that after such a date (1900 recommended) genera proposed or described without species named in connection with them should be considered as being without status in nomenclature and ignored accordingly, as newspaper descriptions are ignored. If this is possible, the systematists of the present and future will not have constantly accruing cases of the kind to deal with, or be in danger of their common occurrence, and the old cases would be gradually cleared up.

As to the second class of cases. We may not know, or attempt to define, the exact differences between a species and a genus in monotypical genera; still we do know as a matter of experience that when an author briefly defines a new genus in a diagnostic table of genera of a group and merely mentions a species as type, without describing it and yet follows the rules of binary nomenclature, he has not done all that is necessary to make it recognizable. As a matter of fact, we know that he has not described the species by diagnosing the genus, for the simple reason that the species can not be recognized. As a case in point: In a group of insect parasites of the Hymenoptera, the late Dr. Ashmead, in a table of the genera of a tribe of the Sphegisterinae describes or defines a new genus called *Pachycrepoides*, merely naming a type

¹ N. S., XXIX., February 26, 1909, pp. 339-340.

species in parentheses, without describing it. As defined, the genus was based on but one or two general diagnostic characters. Just recently, I had occasion to deal with the genus in connection with certain parasites of the common house-fly (*Musca domestica* Linnaeus); the species of parasite agreed with the brief description of the genus in every particular, as far as it went. The question arose, was it the type species. To decide from the description of the genus was nothing less than pure guesswork. *The generic description or diagnosis did not characterize the species.* Fortunately, I knew that the type species was in the National Museum at Washington and through the kindness of the authorities of that institution I learned that the species which I had under consideration was not only not the type species of *Pachycrepoides*—a fact which was not strange—but that it differed so much from the genus itself, in other structural, generic characters not mentioned in the description, that it formed a distinct genus in the same division of the tribe.* This case is but one in a number of similar ones which occur in the parasitic Hymenoptera. To say that the type species of this genus is described is to say, it seems to me, that naming a thing describes it. To hold such a view is to recommend the practice of naming instead of describing, which is practically what the case just cited amounts to. It is merely another way of saying that to generalize on the whole, is describing and making recognizable all of the component parts. As genera are being described at the present day, even, the practice is a most dangerous one, for unless the type species are soon described they become unrecognizable, the genera practically come under the first class of cases considered, and progress demands a removal of the obstructions and they fall or have to be reconstructed. Future cases of this kind should be prevented.

The main point to which I wish to call attention, however, is not what to do in past cases of the kind considered, but what to do in order to prevent their occurrence in the

*I have since learned that my species was the type species of *Pachycrepoides*. This does not alter the case.

future. In this matter, we must leave the past behind us and build for the future. Looking ahead, not behind, the whole question of nomenclature turns on a single point, that of identity. If those who come after are to build upon what we are doing in the present, stability in nomenclature will primarily depend on the means we leave behind us for the identification of the things we name. Nomenclature, as we all know, is but the tool, the means to the end of systematic work; the end is fundamentally concerned with identity, identity based on, and dependent upon, definition or description. In the great present-day activity in systematic work, enlightened by past failures and errors, it seems to me to be a deliberate fault for a systematist to cause cases like the kind we have considered. We must all know that what in the far past was regarded as a genus, to-day has become a family or other higher group, and in all probability what is regarded as a genus to-day, in the future may become a much higher group. We have all learned, ere this, that the greatest causes of error, delay and obstruction to progress in systematic zoology at the present time is the meagerness of definition or description of genera and species. Of what use is it to us, to the future, to the race at large, to science, for a systematist, although a recognized authority in the group in which he is working, to describe briefly, unrecognizably, new genera or new species? Does the fact that we know through his efforts that they exist help any of us, help science? Assuredly not; if the units are not recognizable they are nothing more or less than obstructions. Fifty years hence, the systematists will be considering them under the same general classes of cases that we at the present are considering the poorly described genera and species of fifty or more years ago. Having what will then be considered but one or two very general diagnostic characters upon which to base conclusions, in all probability they will be at an utter loss to know into what families or other groups to place them. Of what possible benefit is it, therefore, to describe these things unless we use in every case all the means at our command to make them

recognizable; will they not in the end become mere *nomina nuda*?

Identity being the fundamental basis of nomenclature, and intimately connected with the end of systematic work itself, it seems utterly absurd to ignore it or to give it but passing attention. Therefore immediate steps should be taken to insure it. Instead of having an international code of nomenclature recommended to zoologists, to be followed at their discretion, we have advanced far enough to have one which should be enforced by legislation of some such body as the International Zoological Congress, no systematist being recognized unless adhering rigidly to its rulings. At first thought this step may appear to be visionary, as we can not by law control such intangible or incorporeal things as the individual judgments of men concerning what is or is not a good description of a thing; nevertheless, we can prescribe, in cases of the kind considered, what shall or shall not be done in the future. Genera described without species can be rigidly barred; genera described without a description of the type species upon which they are based can be treated likewise. The authors of such genera could be reprimanded or discountenanced, in a sense prescribed. Further a date of departure for a new system of nomenclature based on the future should be designated, for the questions of the past should be studiously avoided in the future, and the new code should be conceived in the spirit of the future, that is to say, in the spirit of expansion, of progress. Such a code, for instance, could provide for the future cases coming under article 21 of the international code, which should be framed along lines tending to make descriptions infinite in detail. For example, an *indication* should not be allowed to hold for present-day or future descriptions and some provision should be made for the compulsory deposition of types in accredited museums. I have mentioned but one or two points which such a code should be expected to cover; for its development and adoption I can hope only; for these few suggestions, I beg the consideration due to the spirit in which they are offered.

The end should always be in mind; we must

broaden our view-point; let us look to the future, for properly the present belongs to it.

UNIVERSITY OF ILLINOIS,
March 1, 1909

SCIENTIFIC BOOKS

The Origin of the Vertebrata. By WALTER HOLBROOK GASKELL. Longmans, Green & Co. 1908.

Professor Gaskell during the past two decades has published an extended series of papers which have aimed to convert morphologists to the view that vertebrates are descended from arachnids. These papers, with additions and corrections, are now brought together in volume form. We suggest, however, the book's title "*The Origin of the Vertebrata*" is chosen inaptly. It should have read "*The Supposed Arachnid Origin of the Vertebrata*," or, better, "*A Plea for the Rejected Theory of the Origin of the Vertebrates from Arachnids*." For it is hardly fair that the purchaser of this book should believe that he has here a résumé of our knowledge of the ancestry of the vertebrates. He is given merely a one-sided view of the whole intricate problem.

It is just to say that Gaskell has devoted himself generously to the task which he has sought to accomplish. His work shows that he has been earnest and tireless, that his reading has covered a field much wider than that of the usual promoter of a lost cause—that he is not one of those whose effort is measured in terms of success, for he would himself admit that even his friends (and he has many sympathetic ones) in the wide zoological fraternity, do not subscribe (there is scarcely an exception) to a single tenet of his heretical morphology. If he had been trained as a morphologist instead of as a physiologist, perhaps he himself would never have developed his theory.

There has been of late years a tendency to ignore Gaskell's writings on the ground that his arguments, having been weighed carefully, have been found wanting. Then, too, we have lost zest for discussing his difficult theses, *e. g.*, that the arachnid gut and nervous cord fused

to establish the tubular vertebrate nervous system; that the vertebrate gut is a new structure formed by the fusion of the bases of arachnid appendages; that the notochord was later formed from this new gut; that the arachnid genital ducts were retained as the vertebrate thyroid; that the arachnid genital tissue and liver became converted into the arachnoidal fat which fills the brain-case and invades even the skeletal capsule of the vertebrate ear; that Kupffer's sensory plakodes are reminiscent of arthropod appendages; that coxal glands are the homologues of both the pronephros and thymus; that the wide discrepancy in the plan of the embryonic development of arthropod and vertebrate, as in the inversion of the dorso-ventral orientation, is a mere detail caused by the shifting of the mass of the yolk.

One hesitates at this day to reopen an indigestible discussion. And it would be profitless were it not that the volume has brought forward the theory in such a pleasantly written and well-published fashion, which will give it in all probability a wide circulation. The present review need comment on but a few of its teachings—those which touch fundamental conceptions in morphology.

I. Gaskell maintains the doctrine that evolution proceeds (genetically) from the dominant type of one geological horizon to the dominant type of the following geological horizon. This is a doctrine which at the best is intangible and unconvincing. Even the example cited by Gaskell does not support his case—that the vertebrates in their earliest occurrence superseded the sea-scorpions of the early Paleozoic. For at that critical time it was the cephalopods (*e. g.*, the huge *Orthoceratids*), not the sea-scorpions, which were the dominant race. However, for the sake of argument, granting that the cephalopods are lower than arachnids, they are obviously much higher (measured by the standard of the nervous system) than the lower crustaceans or the worms, hence by the doctrine of dominant types they should have taken an intermediate genealogical position between the crustacea and the arachnids, which even Gaskell would deny.

II. Gaskell seems to have little conception

of parallelism, and he is probably, therefore, unaware of the mighty literature dealing with his theme. This is the more regrettable, since it is this principle which bears so directly upon phylogenetic studies. For it can now be demonstrated beyond peradventure that animals, *e. g.*, of different orders, may develop similar structures to such a degree that they are sometimes mistaken for members of the same family or even genus. And if this be true, how can we believe that certain specified resemblances of king-crab to vertebrate can be accepted as tests of genetic kinship? If such a form as a *Litoptern* can develop many essentials of a horse, yet be not included within the great group of Ungulates, how can we accept Gaskell's elaborate details when he compares forms as widely apart as a vertebrate and an arachnid? An arachnid has no tubular nervous system, no gill slits, no notochord; it has widely different appendages, skeleton, skin, urogenital system, sense organs—how therefore do we venture to compare its details with such vertebrate structures as the abducens, or the various branches of the fifth nerve, or the jaw muscles? We might, in fact, make a comparison of this kind as convincingly, or unconvincingly, by selecting the structures of a cephalopod. In a word, it is this kind of comparison which makes the distressed reader cast down Gaskell's book even when assured by the author that the evidence of these "homologies amounts almost to a certainty."

III. Gaskell fails to take into account a fundamental rule in descent study, that *series* of forms whose structures are the most closely connected should be used for comparisons. This rule he violates constantly when he compares the Paleozoic *Cephalaspis* and the recent lamprey-larva, *Ammocetes*, for these forms are by no means the nearest links in a possible chain. As a matter of fact, we now know that *Cephalaspis* is but one example of a great group of Paleozoic creatures, that these creatures show the greatest range in forms and structures, and that many of them are unlike arachnids even in superficial regard, in fact some of them are soft-bodied and covered with shagreen like a

shark. It is, accordingly, by no means to be accepted that these creatures are nearly akin to *Limulus*, even if cases of superficial resemblance be pointed out. For the general outward shape of *Limulus* may be acquired independently by creatures of very different groups, even to a certain degree among vertebrates by rays and siluroids. On the other hand, it is clear that ammocetes should be compared at first not with a Paleozoic form of dubious kinship, but with other cyclostomes, especially with the hag-fishes, which Gaskell rarely mentions. The fact is that after comparison with the latter forms, we are less inclined to regard the ammocete as a primitive and unmodified creature. For we find that the hag-fishes have no metamorphosis, and we may, therefore, more easily harbor the suspicion that the exceptional sand-living life habit of the larval lamprey has been responsible for many of its curious features, and that these have no wider phylogenetic bearings than have, for example, the peculiar larvalisms developed by many teleosts. But let us not go into details. The momentous problem of vertebrate beginnings is still "on the knees of the gods." We gravely doubt whether Gaskell's book will be of great value in dislodging it.

BASHFORD DEAN

Modern Thought and the Crisis in Belief.

The Baldwin Lectures, 1909. By R. M. WENLEY. New York, Macmillan. 1909. Pp. ix + 364.

This volume results from the nomination of Professor Wenley by the Protestant Episcopal Bishop of Michigan to give a series of lectures in an endowed course "for the Establishment and Defence of Christian Truth." The circumstance will, perhaps, not especially commend the book to the interest of some readers of this journal. Few ways of spending money seem to some modern minds less desirable, or more productive of ethically awkward situations, than the creation of permanent foundations for scholarly inquiries or discussions, whose results are predetermined by the terms of the endowment supporting them; this is true whether the predetermined result be the truth of Christianity or the truth of socialism.

With old foundations of this sort we must do the best we can; but it is a somewhat regrettable anachronism that new ones should appear in recent years, and in connection with American universities. One can hardly suppose that the Christian truths which Professor Wenley establishes and defends would have been recognized as such by the episcopal founder of the lectureship, no longer ago than 1885. The book is almost equally divided into a destructive criticism of religious beliefs still current, and philosophical reconstruction; but one apprehends more clearly what it is that is destroyed than what it is that is constructed. The best, and the longest, division of the book deals with a topic that does not call for discussion here: the religious consequences of historical criticism; the outcome is a frank abandonment of the historical character and content of Christianity, and the transfer of interest from a historic teacher to a "metahistorical Christ." The precise ontological status of this entity, and its relation to the historic Jesus, remain obscure to the present reviewer. The other main division of the book concerns the religious bearings and the philosophic validity of the "natural science view of the world"—the doctrine unfortunately labeled by Ward "naturalism," by which appears to be meant a mechanistic cosmology, biology and psychology taken as equivalent to a complete account of the nature of reality. With this, Professor Wenley vigorously argues, religious thought must now have a definite reckoning; for while historical criticism can destroy nothing essential to religion—since nothing historical is essential to religion—naturalism is the "executioner of the ideal life." Since the refutation of naturalism is presented as the main task, not only of this book, but of the present age, one is disappointed to find Professor Wenley devoting expressly to it only some forty pages—one ninth of his space. It should be said, however, that the author regards the task as one for the most part already accomplished, by Ward's "Naturalism and Agnosticism," which he here, so to say, reenacts. His own argument rests chiefly upon two points: (1) Every science begins by deliberately abstracting certain as-

pects of the world from their context, which none the less really conditions them; the conclusions, therefore, of any science become, if generalized and made applicable to the whole, not only inadequate but self-contradictory. (2) Likewise, if the generalized results of science conflict with ideal interests they stultify themselves; for the abstraction from which they arose was for the sake of an ideal. While the reviewer sympathizes with much in Professor Wenley's doctrine, he does not think these arguments calculated to convince. (1) To say that the conclusions reached primarily by segregating and analyzing a certain aspect or type of phenomena are *necessarily* inapplicable and absurd beyond the limits of that segregation, is to say that no unification of knowledge is possible at all. Science assumes that phenomena seemingly complex and diverse can ultimately be understood as special variations—under conditions also generalizable—of a simple and homogeneous type-phenomenon, or of a few such. This assumption is very possibly unwarranted; but it is not comic, and it is not to be disposed of by so easy a piece of dialectic as that employed by the author. (2) Many principles of science are undoubtedly postulated ideal demands. There is no necessary paradox in the opposition of these intellectual ideals to ideals of another order and origin. The question—which this book does not very explicitly discuss—is: When they conflict, which has the right of way?

One could wish that Professor Wenley would be persuaded to chasten his style. At its best it is admirably vigorous and effective; but there are moments in which it seems a cross between the style of the Delphian oracle and that of Mr. George Ade. In such passages the simple, precise and natural expression is laboriously avoided in the interest of strange archaisms and neologisms and a general grandiloquent incomprehensibility. Thus the reader is told that "a mystic element is the *leit motiv* of the fiducial process"; what he is expected to gather is uncertain, but the reference at any rate is *not* to the religious propensities of bankers. One learns of "the ~~mean~~ means whereby acute need for God is

brought home to the secular group"; one is warned that "while it would be sheer ingratitude to lightly these [historical] investigations, it is quite another affair to train with their representatives when," etc.; one is assured that "God is the normative content of human life"; and one makes the acquaintance of such supernumeraries of our speech as "to gift a procedure" (meaning, simply, to give a procedure), "derivant" (for derivative), "a quantitative phantasmagoria," "misfortunately," "his near kith."

ARTHUR O. LOVEJOY

THE UNIVERSITY OF MISSOURI

ON THE NATURE AND POSSIBLE ORIGIN OF THE MILKY WAY¹

WHILE the milky way has long been recognized as a relatively thin segment of space in which stars appear more numerous than elsewhere, no satisfactory explanation has been offered for the existence of such a segment with the earth apparently at its center or for any of its characteristic peculiarities of aspect and relationship to the stars as a whole. Noteworthy among the features calling for explanation are the following: The milky way is a belt approximately following a great circle of the sky but broad and diffuse throughout one half of its course while relatively narrow and well defined on the opposite side. The broad half of the belt is cleft in two by a dark lane running along its axis and in addition contains numerous rifts and holes from which the narrow half is relatively free. The number of stars per unit area of the sky is a maximum in the milky way and diminishes progressively on either hand, while the inverse relation is true for the nebulae, their frequency increasing with increasing distance from the milky way.

It is shown in the present paper that all these peculiarities are immediate results of the supposition that the visible universe consists in the main of two distinct but interpenetrating parts, the first of which is a chaos of indefinite extent in which stars and cosmic

¹ Abstract of paper read at the April meeting of the National Academy of Sciences by George C. Comstock.

dust are distributed with some rough approach to uniformity in general, but with a marked tendency to local aggregations and clusterings. Through this chaos moves the second part, a cluster of stars of great but measurable dimensions, long, broad, but comparatively thin and including the sun as one of its central members. The diameter of this cluster is to be measured in hundreds of light years and throughout at least a large part of its central regions the stars are much more densely clustered than in the external chaos.

In accordance with well-known dynamical laws this moving star stream would operate much after the fashion of a snow plow, sweeping away the cosmic dust from its path and piling it on either hand, above and below the plane of the cluster. The transparent rift thus formed is the milky way through which we see farther and command a view of more stars than through the intensified dust clouds on either side. The dust ejected toward the poles of the milky way constitutes the substance of the nebulae which there abound.

The narrow half of the milky way is that which lies behind the moving swarm, since here we see the accomplished work of ages and look between dust clouds, long since produced, that converge to a vanishing point. Ahead, in the direction of motion, the work of clearing a path is in progress and relatively near at hand, so that the partially cleared space subtends for us a broader angle, in the midst of which there are collected considerable quantities of primordial dust, the slower-moving particles, which have been captured and permanently annexed by the vanguard of the swarm. The annexed dust cloud constitutes the long cleft in the milky way, while its attendant holes and rifts mark unfinished work on the inchoate side of the galaxy.

The interpretation of the milky way here offered must not be judged solely by its consonance with the phenomena above suggested. It must harmonize with every other fact known about the milky way and it has been the task of the author to seek widely for discord as well as harmony between such facts and the theory above outlined, making the test, wherever possible, a quantitative numerical

one. No serious discordance has been found, but the agreement with knowledge hitherto vaguely (or not at all) correlated with the milky way is in some instances striking. Thus the researches of Kapteyn, Eddington and Dyson upon the proper motions of the stars have shown that in the main these bodies belong to two groups in relative motion along the line and in the direction above suggested in explanation of the milky way. Again Pickering has recently announced certain well-marked differences in the distribution of stars of different spectral types, viz., the fainter stars of the galaxy are almost wholly of the first (Sirian) spectral type. The number of stars of the first type increases with diminishing brightness in a four-fold ratio for each successive magnitude, as theoretically it should increase if these stars were uniformly distributed through infinite space. Per contra, stars of the second type (solar) increase from magnitude to magnitude only in a ratio represented by the number 3.25, thus implying a distribution very unlike that of the first type stars. All three of Pickering's propositions, together with similar ones earlier formulated by Seeliger for the totality of stars, without distinction of spectral type, are numerically accounted for by the supposition that the stars composing the primitive chaos are mainly of the sirian type while those of the solar group are predominantly of the solar type. By direct enumeration Eddington finds that this relative predominance of spectral types is shown in the two groups into which the stars are divided with reference to their systematic proper motions.

It is easily seen to be a necessary corollary from this explanation of the milky way that stars in or near the galaxy should on the whole appear to move more slowly across the sky than do similar stars remote from the milky way, and that this predicted result is in fact true has been shown by at least two astronomers. Another interesting corollary may be derived through the supposition that a star belonging to the solar group may by virtue of its motion be made to pass so near to one of the sirian stars as to produce disturbances, one upon the other, that will long remain

marked by some peculiarity of spectrum. If such were the case the stars so marked should be found only in or near the milky way and they should be especially numerous and compactly clustered astern of the solar group, they should be more sparsely distributed ahead of it and should be almost completely lacking on either side of the procession. The so-called Orion stars constitute just such a set of objects, marked and distributed as above and presenting the further peculiarities that their apparent motion across the sky is abnormally small and that their number shows no tendency to increase as we pass from the brighter to the fainter magnitudes. All of these characteristics are such as would be possessed by stars formed as above suggested.

In a somewhat similar class are the new or temporary stars believed to result from collisions of some kind and found only in or near the milky way. Why they are limited to the milky way is now apparent, since that is the region, according to the present hypothesis, in which large relative motions are to be expected.

We may look upon double stars as produced by the close approach of a solar to a sirian star under circumstances such that the gravitational bond between them becomes too strong to be broken and the two bodies abide thenceforth in enforced partnership. The size and shape of the orbits in which they shall move about their common center of gravity are determined by the circumstances of their meeting and an elementary analysis suffices to show that the circumstances that tend to produce a small orbit will equally tend to make that orbit nearly round, while those which make a large orbit will equally tend to make it more pronouncedly oval. A statistical examination of double stars shows that they do in fact show this relation among themselves, a small major axis being predominantly associated with a small eccentricity, an agreement between fact and theory that can hardly be accidental.

The test of a valid theory is its power to coordinate apparently unrelated facts without coming into conflict with any of them and, in view of the illustrations of such coordina-

tion given above and of others for which space does not here suffice, there is here presented the concept of a definite group of stars moving through a much more widely extended chaos as the best working hypothesis at present attainable with reference to the stellar system.

BOTANICAL NOTES

OUT OF DOOR BOTANICAL STUDY

WITHIN a few weeks students who are planning out of door study in the summer vacation will decide where they will go. In the hope of being able to help such students to decide wisely we here bring together in summary form abstracts from the announcements made by the directors of half a dozen laboratories.

The oldest laboratory of this kind is the Marine Biological Laboratory at Woods Hole, Mass., whose twenty-second session extends from June 1 to October 1. In addition to instruction in botany, zoology, embryology and physiology, opportunities are afforded for investigation in these departments of biology. For botanical students instruction is offered (1) in the morphology and taxonomy of the algae, and (2) the morphology and taxonomy of the fungi. Five buildings with fifty-five private rooms for investigations, and seven general laboratories, constitute the plant, and are supplied with aquaria, collecting apparatus, reagents and glassware. The laboratory has a steam launch, boats, dredges and the apparatus necessary for collecting and keeping alive material for class use or research. Dr. George T. Moore, of Water Mill, N. Y., is in general charge of the botanical work.

The twentieth session of the Biological Laboratory at Cold Spring Harbor, Long Island, begins July 7 and closes August 21. Opportunities for instruction and investigation in botany and zoology are offered. In botany the instruction includes courses in: (1) Cryptogamic botany—especially algae and fungi, and (2) ecology. The laboratory possesses three buildings for study purposes, supplied with needed appliances, and five dormitories, accommodating seventy-five persons. A 28-foot motor boat, with small boats,

collecting apparatus, etc., are supplied. Professor D. S. Johnson, of Johns Hopkins University, Baltimore, Md., is in general charge of the botanical instruction.

The tenth session of the Harpswell Laboratory at South Harpswell, Maine (sixteen miles from Portland), will be held June 14 to September 11. The laboratory is intended for research students only, and for their accommodation has one building affording facilities for fifteen persons. A motor launch, small boats, nets and dredges are provided for collecting, while in the laboratories are glassware, aquaria, microscopes, microtomes, etc., for the work of investigations. Professor J. S. Kingsley, of Tufts College, Mass., is in general charge of the laboratory.

The Minnesota Seaside Station at Port Renfrew, on the west coast of Vancouver Island, will resume its sessions this year, after a vacation of a year. There are two laboratory buildings, and one dormitory and mess hall, for the use of students. The large brown seaweeds are more than usually abundant along the coast near the station, while the forests of this part of the island are wholly unbroken. The session begins about July 6 and ends about the middle of August. Professor Josephine E. Tilden, of the University of Minnesota, Minneapolis, Minn., is in general charge of this station.

The first session of the Marine Biological Laboratory of the Washington State College will be held at Olga, on Orcas Island, in the northerly part of Puget Sound, beginning June 21 and continuing to July 30. The immediate surroundings include the open waters of the sound with their rich marine flora, the tide flats, open land, forests, nearby fresh-water lakes, Mt. Constitution (2,400 ft. alt.) with ravines, waterfalls, swamps, etc. A motor launch, row boats, dredges, collecting apparatus, microscopes, etc., are supplied. Instruction and opportunities for investigation are offered in botany and zoology. Professor R. K. Beattie, State College, Pullman, Wash., is in general charge of this station.

Allied to the foregoing is the Mountain Laboratory of the University of Colorado, whose first session will be held (June 14 to

July 24) at Tolland, Colorado, in a mountain park at an altitude of nearly nine thousand feet altitude above sea-level. This point is eighteen miles southwest of Boulder, and is in the midst of hills, mountains, moraines, ravines, brooks, mountain meadows and ponds. The rich forest vegetation of the near-by region, and the "timber line" and alpine vegetation within easy reach, afford many interesting ecological problems. Courses in general biology, nature study, plant ecology, anatomy and taxonomy are offered, and opportunities are given for individual work and investigation. Professor Francis Ramaley, of Boulder, Colo., is in general charge of the laboratory.

SOME SOUTH AFRICAN BOTANY

FROM far-away South Africa comes a handful of papers by Professor Joseph Burt-Davey, the agrostologist and botanist for the Transvaal Department of Agriculture. Quite naturally these papers have a strong agricultural bias, yet in all of them the scientific botanist may find much that will throw light upon the native vegetation of the region. One of the most interesting of these papers is that on the "Native Trees of the Transvaal" (1907), in which 269 species, representing 57 families, are recorded, and the additions made during the following year and reported in another paper, bring these numbers up to 336 species and 58 families. These are distributed through four well-marked zones, viz: (1) "The Mist-belt Forest" on the upper eastern slopes of the Drakensberg mountains, where the rainfall is heavy and the atmosphere humid. "A characteristic feature is the evergreen character of the trees, the common occurrence of epiphytes, lianes and ferns":— (2) "The High veld zone," consisting of a typical grass-steppe region, in which trees are rare. It descends to about 4,000 feet altitude: (3) "The Middle veld zone," known also as the "Bush veld," and for the most part loosely covered with trees so as to constitute a "Savannah" region rather than a real forest: (4) "The Low veld zone," restricted to the country lying below 1,500 feet altitude, and also a "Savannah" region.

Looking over the lists one notes species of *Pedocarpus* (*Taxaceae*) and *Callitris* (*Pinaceae*), *Phoenix* and *Hyphaene* (*Palmaceae*), many genera and species of *Anacardiaceae*, *Celastraceae*, *Ebenaceae*, *Flacourtiaceae*, *Leguminosae*, *Moraceae*, *Proteaceae* and *Rubiaceae*. Very few of the genera are identical with ours, although one may find such names as *Rhus* (with over 20 species), *Ilex*, *Diospyros*, *Euphorbia*, *Vaccinium*, *Ricinus*, *Acacia*, *Mimosa*, *Cassia*, *Ficus*, *Olea*, *Rhamnus*, *Cephalanthus*, *Xanthoxylum*, *Salix*, *Celtis*. Aside from these the genera are quite unfamiliar to the American dendrologist.

The other papers include such topics as the breeding of maize, ramie cultivation, plants poisonous to stock, and the cultivation of alfalfa (lucerne). The latter is very full, and includes over eighty pages, with a number of illustrations.

A NEW BOTANICAL JOURNAL

EARLY in the year (February 27) the first number of a new journal appeared under the name *Mycologia*. On the title-page it is said to be "in continuation of the *Journal of Mycology* founded by W. A. Kellerman, J. B. Ellis and B. M. Everhart in 1885." It is to be "published bimonthly for the New York Botanical Garden." About the middle of April the second (March) number appeared, and we are thus able to judge as to what the new journal is to be like. The first number contains a good colored plate of agarics and pore fungi, and one black-and-white plate. The text includes twenty-six pages, and the articles are entitled "Illustrations of Fungi, I.," "The Boletaceae of North America," "Notes on North American Hypocreales, I.," "A Bacterial Disease of the Peach," "The Problems of North American Lichenology" and "Notes and News." The second number contains one colored plate of agarics and three black-and-white plates, and the text includes forty-six pages. The papers are, "Illustrations of Fungi, II.," "The Hypocreales of North America, II.," "Filling Tree Cavities" and "Notes and News."

The journal is well printed and is a worthy continuation of the *Journal of Mycology*.

At the moderate price of three dollars per year it will, of course, be indispensable in every botanist's library.

LEO ERRERA

NEARLY four years ago the noted Belgian botanist Leo Errera died in his forty-seventh year. Born in 1858, he very early displayed a brilliancy of mind which indicated what he was to become in his maturity. Receiving his doctorate from the university, he studied also with Sachs, DeBary, Hoppe-Seyler, Waldeyer, Stahl and others, and became personally acquainted with Bower, Vines, Klebs, Schimper and other noted botanists of Europe. Then began a life of incessant activity, during which he prepared and published nearly three hundred papers. The earliest of these appeared when he was but a youth of seventeen years, while the last ten appeared within a year or two after his death, after having been completed by willing friends.

There is now appearing in Brussels a collection of the works of Errera under the title "Recueil d'Oeuvres de Leo Errera" which is to be completed in six volumes. The papers thus brought together (and they are a selection from all his publications) are of two kinds, viz., (1) those addressed exclusively to specialists in botany and physiology, and (2) those intended for "non-specialists who read and think." Those volumes have already appeared, viz., I. and II., devoted to general botany, and VI., containing miscellaneous papers in prose and verse. The third volume is to be devoted to general physiology, the fourth to philosophy, while in the fifth will be found pedagogical and biographical papers. The beauty of these volumes, their good paper and clear type commend them as a fitting memorial worthy of the man whom they honor.

UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

DETERMINATION OF THE COEFFICIENT OF CORRELATION

IN statistical work it is often necessary to determine the coefficients of correlation between a number of variables, the calculation

of which according to the usual method of correlation tables occupies much time, while the subdivision into larger groups makes the results inaccurate. The following method of calculation secures a great saving of time and labor. The averages and mean square variabilities of all the variables must be determined. By forming the differences between any series of pairs, we find the values of $x - y$, which may be treated like any variable. Indicating averages by brackets, we have

$$\begin{aligned} [(x - y)^2] &= [x^2] + [y^2] - 2[xy] \\ &= \sigma_x^2 + \sigma_y^2 - 2r\sigma_x\sigma_y \\ -r &= \frac{[(x - y)^2] - \sigma_x^2 - \sigma_y^2}{2\sigma_x\sigma_y} \end{aligned}$$

For a single correlation there is not much saving of time in this method of calculation, but in multiple correlations a very large amount of labor is saved.

A similar device may be used in the calculation of correlations of fraternities. When the deviations for members of a fraternity are designated by $x_1, x_2, x_3 \dots x_n$,

$$[(x_1 + x_2 + x_3 + \dots + x_n)^2] = n\sigma_x^2(1 + n - 1r)$$

$$r = \frac{[(x_1 + x_2 + \dots + x_n)^2] - n\sigma_x^2}{n(n-1)\sigma_x^2} = \frac{1}{n-1}$$

A similar method will allow the determination of the average correlation of a large series of variabilities. By reducing each variable to multiples of its variability, we find

$$\left[\left(\frac{x_1}{\sigma_1} + \frac{x_2}{\sigma_2} + \dots + \frac{x_n}{\sigma_n} \right)^2 \right] = n + r_{1,2} + r_{1,3} + \dots + r_{n-1,n}$$

$$[r] = \frac{\left[\left(\frac{x_1}{\sigma_1} + \frac{x_2}{\sigma_2} + \dots + \frac{x_n}{\sigma_n} \right)^2 \right] - n}{n(n-1)} = \frac{1}{n-1}$$

Correlations of phenomena that can not be measured, but only counted, may be treated in the following manner: If two events that have the probabilities p_1 and p_2 are correlated, we may say that those cases in which the event 1 occurs have the probability 1, or a deviation from the normal probability $1 - p_1$.

Those cases in which the event 1 does not occur have the probability 0, or a deviation from the average probability of $-p_1$. If we call p_1' the probability of the event 2 when event 1 occurs, p_1'' the probability of event 2 when event 1 does not occur, and q_1 the coefficient of regression of 2 upon 1, we have

$$\begin{aligned} p_1' - p_2 &= q_1(1 - p_1) \\ p_1'' - p_2 &= -q_1p_1 \end{aligned}$$

Thus the phenomenon corresponds strictly to that of measurable variables, and the procedure may be followed that is applied in the calculation of the coefficient of correlation of measurable variables. It follows that

$$p_{1,2} = p_1p_2 + q_1p_1(1 - p_1)$$

We designate, as usual,

$$\begin{aligned} q_1 &= r \frac{\sigma_2}{\sigma_1} \\ q_1 &= r \sqrt{\frac{p_2(1 - p_2)}{p_1(1 - p_1)}} \\ p_{1,2} &= p_1p_2 + r \sqrt{p_1(1 - p_1)p_2(1 - p_2)} \\ r &= \frac{p_{1,2} - p_1p_2}{\sqrt{p_1(1 - p_1)p_2(1 - p_2)}} \end{aligned}$$

The correlation between a measurable and an unmeasurable quantity can be determined in a similar manner. When the measurable quantity is grouped as an array of the measurable quantity, we find, using the same symbols as before,

$$\begin{aligned} [x'] &= q_1(1 - p) \\ [x''] &= -q_1p \\ \therefore [x'] - [x''] &= q_1 \\ \text{or } q_1 &= \frac{[x']p}{p(1 - p)} \\ r &= \frac{[x']p}{\sigma_x \sqrt{p(1 - p)}} = \frac{-[x''](1 - p)}{\sigma_x \sqrt{p(1 - p)}} \end{aligned}$$

From these formulas, multiple correlations may be calculated according to the same formulas as those used for measurable variables.

FRANZ BOAS

COLUMBIA UNIVERSITY

THE ENZYMES OF OVA—INFLUENCED BY THOSE OF SPERM?

SOME few summers ago, while working in the laboratories of the Biological Station at Woods Hole, Mass., the writer began some experiments to ascertain whether or not the action of the enzymes of ova were in any measure increased or decreased by those of sperm. The problem was suggested by the work of other investigators which showed that some enzymes have an interdependent action. It was also conceived that the process of fertilization might be due to the acceleration of

the enzyme action of the eggs by virtue of the presence of the enzymes of the spermatozoa. If such were the case the accelerated enzyme action might be demonstrated in the test-tube.

The results of the tests were in no measure conclusive, and the writer had hoped that he would have an opportunity to pursue the problem further, and for these reasons no reports on the investigation were made. As it seems that the work in which the writer is now engaged will prevent his having opportunity to repeat the experiments, a succinct general report of the work will here be made.

Star fish were chosen because they afforded a plentiful supply of both eggs and sperm, and because they were easily obtained from the waters about Woods Hole. The males and females were carefully washed and kept separate. The eggs and sperm were thoroughly ground by mortar and pestle; the power of each to split starch, fat and hydrogen dioxide was tested. Three tubes were used in each case. In tube 1 was placed 5 c.c. of ground eggs, 5 c.c. of starch solution and 5 c.c. of water. In tube 2 was placed 5 c.c. of ground sperm, 5 c.c. of starch solution and 5 c.c. of sea water. In tube 3 was placed 5 c.c. of the ground eggs, 5 c.c. of the ground sperm and 5 c.c. of the starch solution. The tubes were allowed to stand at room temperature for a considerable time, after which the contents were tested for sugar by the reduction test. It was found that there was only the slightest trace of reducing substance in tubes 1 and 2, whereas in tube 3 there was a very distinct amount present. These experiments were repeated perhaps six to ten times and the results were conflicting. They were neither consistently negative nor consistently positive. Nor were they sufficiently often positive to convince one that when they were positive it was not an accident. Comparable experiments to the above were carried out with butyric ether and hydrogen dioxide. The results were equally exasperating as those with starch. Whether the positive results were entirely the result of error or whether the negative results were due to the use of unmaturing eggs or sperm it is impossible to say. It seems, however, that the results were such as to justify a

careful repetition of the experiments, and it is hoped that some capable man who is interested in the problem will take it up.

It is a well-recognized fact that a large number of the female star fish contain a large number of eggs that appear in every way normal, mature and ready for fertilization and yet will not develop when sperm is placed with them. It seems that it may be possible that this would account for the varying results.

ORVILLE HARRY BROWN

NOTE ON THE ACCESSORY CLEAVAGE IN THE
HEN'S EGG¹

HARPER² has shown that polyspermy normally occurs in the pigeon's egg. His figures indicate that from twelve to twenty-five sperm-nuclei are formed in the egg. Only one of these, however, becomes a functional sperm-nucleus; the others migrate from the points of entrance to the periphery of the disc where they become active, dividing and giving rise to the "accessory cleavage." There is thus formed around the primary cleavage, which is produced by the divisions of the segmentation nucleus, an area of small cells. Blount³ has later shown that these supernumerary sperm-nuclei live but for a short time, and then degenerate. She estimates the time of their disappearance as coming between ten and twelve hours after fertilization.

In the hen's egg accessory cleavage has neither been figured nor described. On taking up the study of the early development of this egg I was, therefore, greatly surprised to find an accessory cleavage. Not only can the furrows be seen in the living egg, but I also have preparations of surface views in which they stand out with diagrammatic clearness.

¹Publications from the Zoological Laboratory of the University of Texas, No. 96. The writer is greatly indebted to the trustees of the Elizabeth Thompson Science Fund for a grant with which to carry on this work.

²E. H. Harper, "The Fertilization and Early Development of the Pigeon's Egg," *Amer. Jour. of Anat.*, Vol. III., No. 4.

³Mary Blount, "The Early Development of the Pigeon's Egg, with Especial Reference to the Supernumerary Sperm Nuclei, the Periblast and the Germ Wall," *Biol. Bull.*, Vol. XIII., No. 5.

The earliest stage at which I have observed the accessory cleavage is the four-cell. It takes place outside of the area occupied by the primary cleavage, and the planes of the furrows usually coincide with radii of the disc.

Eight-cell stage of the hen's egg. The egg was taken about twenty hours before the time of laying. *a. c.*, accessory cleavage furrows; *a. c. c.*, a small accessory cleavage cell. The dotted line represents the limit of the area of primary cleavage.

The number of accessory cleavages is at no time great. The greatest number so far observed is shown in the accompanying sketch. The actual number, however, may be slightly greater than is indicated by surface views, because in the sections of at least one egg, I have found that not all of the cleavages come to the surface, but some occur in a horizontal plane. That these cleavages are accessory is evidenced by the fact that their accompanying nuclei greatly simulate the supernumerary sperm-nuclei figured by Harper for the pigeon.

Shortly after the stage figured above the accessory cleavages disappear. A detailed study of sections will have to determine whether their disappearance is to be correlated with the degeneration of the supernumerary sperm-nuclei, as reported for the pigeon.

In conclusion it may be said that polyspermy, accompanied by accessory cleavage, normally occurs in the hen's egg. If the number of accessory cleavage furrows may be taken as a general index to the number of accessory sperms entering the egg, it is evident

that polyspermy in the hen is not nearly so great as in the pigeon.

J. THOS. PATTERSON

UNIVERSITY OF TEXAS

THE AMERICAN PHILOSOPHICAL SOCIETY

THE general meeting of the American Philosophical Society was held at the hall of the society on Independence Square, Philadelphia, on April 22, 23 and 24. The opening session began at two o'clock on Thursday, April 22, with President Keen in the chair, and morning and afternoon sessions were held on Friday and Saturday. Vice-president Michelson was in the chair during the session devoted to the papers in physics and Vice-president Scott at that at which the geological papers were considered. The evening of Friday, April 23, was devoted to a Darwin celebration commemorative of the centenary of Charles Darwin's birth and of the fiftieth anniversary of the publication of the "Origin of Species," at which addresses made by the Right Honorable James Bryce, the British Ambassador, on "Personal Reminiscences of Charles Darwin and of the Reception of the 'Origin of Species'"; by Professor George Lincoln Goodale, of Harvard, on "The Influence of Darwin on Natural Science," and by Professor George Stuart Fullerton, of Columbia, on "The Influence of Darwin on the Mental and Moral Sciences."

On Saturday afternoon there was a symposium on earthquakes at which papers were presented by Professor Edmund O. Hovey, Professor William H. Hobbs and by Professor Harry F. Reid. Aside from the three papers presented at the Darwin celebration on Friday evening, forty-four papers were read at the morning and afternoon sessions. A list of these papers with a brief summary of their contents follows:

The American-British Atlantic Fisheries Question: THOMAS WILLING BALCH, of Philadelphia.

This controversy, which is more than a century old, will shortly be submitted to The Hague International Court for settlement. As in the case of the Alaska frontier, where Canada's land claims grew greater with the passing of years, so in this fisheries dispute the position of America on the one hand and of Great Britain, Canada and Newfoundland on the other, is admirably summed up in the words with which the Russian plenipotentiary, Count Nesselrode, defined the positions and arguments of Russia and England when they were discussing the Russo-British American frontier: "Thus we wish to conserve and the English companies wish to acquire."

The Nation and the Waterways: Professor LEWIS M. HAUPT, of Philadelphia.

A philosophical discussion of the relation of the states and the national government in relation to the waterways of the country, in which it was pointed out that the lack of a proper distinction between local, state and national improvements has led the government to assume jurisdiction over all waterways and has thus retarded the symmetrical development of the trunk lines in connection with their feeders by the inability to systematically exclude all these works at the same time. The remedy must lie in the restriction of the governmental control to the strictly interstate waterways or trunk lines and principal harbors, while the states should charter, as in times past, local corporations to develop their own internal avenues of trade and power, as has been so satisfactorily done in relation to the overland highways of commerce and is still the practise in New York, Illinois, Massachusetts and other states.

Why America should Reexplore Wilkes Land: EDWIN SWIFT BALCH, of Philadelphia.

Lieutenant Charles Wilkes, U.S.N., first announced to the world in 1840 the existence of a great Antarctic continent, along whose shores he sailed for a distance of 1,500 miles. This coast is known as Wilkes Land. It has not been visited again. Sir James Clark Ross, R.N., Sir Clements R. Markham, ex-pres. R.G.S., and Captain Robert F. Scott, R.N., neither of whom has been there, declare emphatically that Wilkes Land does not exist and should be expurgated from the charts. It should, therefore, be looked on as a patriotic duty for America to verify Wilkes's discovery and get a more careful chart of its shores.

Many of the early discoveries in West Antarctica were made by American sealers, by Swain, Palmer, Pendleton, Morrell and Smiley. Now all their discoveries are being verified and enlarged by men of other nations. The same thing will happen with Wilkes's discoveries in East Antarctica, if America will not wake up. An expedition to verify Wilkes's discoveries would cost perhaps \$100,000; and the best way to start it might be by forming an Antarctic committee, composed of representative scientists and explorers, who would take hold of and push this matter.

At the conclusion of the reading of Mr. Balch's paper the society adopted the following resolution, presented by Rear-Admiral Geo. W. Melville, Mr. Henry G. Bryant and Mr. E. S. Balch:

WHEREAS: The United States in former years made many brilliant discoveries in the Antarctic, including the continent of Antarctica by Charles Wilkes, and

WHEREAS: The United States have not taken any part in the recent scientific explorations of the South Polar region; therefore be it

Resolved, That the American Philosophical Society requests the cooperation of the scientific and geographical societies of the United States, to urge on the navy of the United States and through the general government, that it do make sufficient appropriations to fit a government vessel to thoroughly explore and survey the coast of Wilkes Land, and other parts of Antarctica.

The Volcanic Formation of Java: HENRY G. BRYANT, of Philadelphia.

An account of Mr. Bryant's explorations of the volcanic formations of the island of Java, illustrated by photographs taken by the author.

Machines and Engineering in the Renaissance and in Classical Antiquity: Professor CHRISTIAN HÜLSEN, of Rome.

A description of the methods and engines employed in moving great weights and performing other engineering feats that excite our admiration in the works of antiquity. A precursor of the automobile, a "walking chair," was described, that was operated by man power. The illustrations were drawn from contemporary sources, the earlier from monuments and carvings and the later from prints and drawings, and in many cases contemporary descriptions were cited.

The Brains of Two White Philosophers and of Two Obscure Negroes: Professor BURT G. WILDER, of Ithaca, N. Y.

The brains of Chauncey Wright and of James Edward Oliver were compared with the brains of two obscure negroes, one a mulatto, the other black. The very unusual gyral simplicity of Wright and the mulatto may have a physiologic significance. The black's brain is comparable with Oliver's and is considerably larger than that of a late prominent politician. These and other paradoxes exemplify the importance of securing a large collection of human brains, especially of educated people, for study and comparison.

In discussion, Professor E. A. Spitzka emphasized the need of more material and stated that the average negro brain is smaller than the average Caucasian.

Some Conditions Modifying the Interpretation of Human Brain Weight Records: Dr. H. H. DONALDSON, of Philadelphia.

An account of the brain weight records that have been collected at the Wistar Institute of Anatomy. After the fifteenth year up to the fifty-fifth, the human brain loses slightly in weight and then more rapidly after that period. This slight loss in weight between the fifteenth and fifty-fifth years is attributed to the influence of those diseases which ultimately end in death.

New Evidences as to the Physical Basis of Heredity: Professor EDWIN GRANT CONKLIN, of Princeton.

Some Notes on the Modifications of Color in Plants: Professor HENRY KRAEMER, of Philadelphia.

The problem of modifying plants in a particular direction is attended with much difficulty, yet we see in nature numerous modifications which are due to the environment, or to external factors, although it is claimed by some modern evolutionists that none of the modifications due to food or to change of locality are permanent.

After reviewing the previous work on the control of color in plants, and enumerating the factors which influence the color in flowers, the author gave the results of his own experiments, which were begun in the autumn of 1904 and have been continued up to the present time. Various soils were experimented with, including an artificial soil, and sand to which a special nutrient was added. The chemicals used to modify the color principles were supplied to the plants in the form of solutions of varying strength, or added to the soil in the solid form, solution gradually taking place.

Results with Roses.—Probably the most striking result which the author obtained by the use of chemicals was the production of a red color in the petals of the white rose, *Kaiserine*. The red pigment occurred in the basal portion of the petals, and was produced in the flowers of plants which were supplied with potassium hydrate, potassium carbonate, calcium hydrate and lead acetate. It should be stated in this connection that the *Kaiserine* rose tends to yellowish but not to pink or red, and therefore the red color produced in the petals is a new character. Two explanations for its occurrence are suggested: (1) either the added chemical has reacted directly with a compound already present in the petals, or has induced the formation of an entirely new substance; or (2) the color substance formed in other parts of the plants, as in the leaves, has been transported to the petals through the influence of the chemical.

Results with Hydrangeas.—Since July, 1907, the author has been experimenting with the red-flowering form of *Hydrangea* (*H. Otaksa*). The following results have been obtained: Blue flowers were produced by plants growing in both sand and garden soil when supplied with the following chemicals: potassium and aluminum sulphate, aluminum sulphate and calcium hydrate. In those plants which were grown in sand and which were supplied with nutrient and potassium carbonate, blue flowers were also produced.

The flowers remained pink or red either when growing in soil or when growing in sand and fed with nutrient and supplied in addition with iron and ammonium sulphate, or lead acetate. In the plants fed with lead acetate the original color was considerably intensified.

In the case of the plants growing in soil and supplied with potassium carbonate there was no change in color, that is, the flowers remained pink, due probably to absorption of the chemical, while as noted above the flowers were changed to blue when growing in sand and supplied with this chemical.

Comparative Leaf Structure of the New Jersey Strand Plants: Professor JOHN W. HARSHBERGER, of Philadelphia.

* Professor Harshberger classified the floral zones of the New Jersey coast district into four regions or "formations"; (1) the beach, (2) the sand dune, (3) the thicket and (4) the salt meadow formations. The character of the flora of each region was dwelt upon, and the leaf structures of the plants adapted to each habitat were described and illustrated. Professor Harshberger believed that studies of this character were necessary to indicate what kinds of plants would have to be grown, if an attempt to reclaim these regions were to be made.

The Composition of Chrysocolla: Professor HARRY F. KELLER, of Philadelphia.

Under this head are included various hydrated silicates of copper, which are amorphous and of rather indefinite composition. The color of these varies from green to blue. The author described a well-characterized variety from Chile, which forms enamel-like crusts of turquoise blue color, having the composition of an acid silicate with two molecules of water of crystallization. He expressed the opinion that the variation in color must be ascribed to the differences in the amount of water of crystallization, the blue varieties containing two molecules while the green varieties contain but one. He is also of the opinion that

many of the varieties analyzed contained admixtures of foreign substances.

The Chemical Work of the U. S. Geological Survey: FRANK WIGGLESWORTH CLARKE, of Washington.

An account of the admirable chemical work of the Geological Survey Laboratory, of which Professor Clarke is the chief, with a review of the more important results of this work.

Recent Work on the Physics of the Ether: PAUL R. HEYL, of Philadelphia.

Considerable interest has been taken of late in the question as to whether the ether is or is not a dispersive medium with regard to light. The work of the speaker, published about a year and a half ago, leads to the conclusion that any dispersion in the ether must be less than one part in 250,000. Since that time others have arrived at the conclusion that there exists a dispersive effect of much smaller magnitude, about one part in a million. There seems to be no doubt of the correctness of their observations, but it is not clear that it is to be attributed to a real dispersive effect in the ether. It is more likely that it is due to tidal phenomena in the atmosphere of the variable stars used as sources of light in the experiments.

The Effect of Bleaching Powder upon Bacterial Life in Water: Professor WILLIAM PITT MASON, of Troy, N. Y.

The extraordinary bactericidal effect of free chlorine or of bleaching powders used in minute quantities in drinking waters was described and it was suggested that an emergency plant for the manufacture of chlorine for this purpose should be attached to the municipal water supplies.

The Detonation of Gun Cotton: Professor CHARLES E. MUNROE, of Washington.

In the use of gun cotton in mines and torpedoes advantage is taken of the discovery of Mr. E. O. Brown that gun cotton which is completely saturated with water may be detonated by the detonation of dry gun cotton in direct contact with it used as a "priming charge," thus securing a large margin of safety for the naval vessels carrying the explosive. Wet gun cotton containing as high as 35 per cent. of water has been shown to be a more efficient rupturing and shattering explosive than dry gun cotton, but the question of how much water the discs of priming gun cotton may contain to be efficient was the object of the research detailed in this paper. The primer was in all cases fired by the service detonator containing 36 grains of mercuric fulminate. The results

show that detonation of the entire charge was effected in every case in which the primer contained less than 12 per cent. of moisture, and occasionally was complete in cases where the moisture ran as high as 15 per cent. and therefore that such gun cotton primers containing not more than 12 per cent. of moisture, fired by means of a detonator containing 36 grains of mercuric fulminate may be relied upon to detonate wet gun cotton with which they are in contact.

The Towadontia: Dr. W. J. SINCLAIR, of Princeton.

South American Fossil Cetacea: Dr. FREDERICK W. TRUE, of Washington.

Dr. True remarked that in connection with a revision of the fossil whales and porpoises of the United States he had had occasion to examine various specimens from Patagonia, including some belonging to Princeton University and to the American Museum of Natural History. Among the former, he found a skull of a new genus allied to the large porpoise of the Amazon River, known as the *inia*, but very much larger. The principal specimen from the American Museum of Natural History was a very finely preserved skull of a little-known genus, *Diocotichus*. This skull is remarkable in possessing large openings through the ethmoid plate, indicating that this porpoise, unlike modern forms, probably possessed a brain with an olfactory lobe and well-developed olfactory nerves, and hence, was endowed with a good sense of smell.

The Patagonian fossil cetaceans thus far known are from the provinces of Santa Cruz and Chubut, and are believed to belong to the Tertiary Epoch. At all events, some of the genera are the same as those found in the Miocene formations of Maryland, New Jersey and other Atlantic coast states.

Some of the Patagonian forms belong to families still represented in South America by living species. Others represent families no longer existing. The fossil fauna includes sperm whales, various forms allied to the *inia*, others allied to *Squalodon*, and at least one species of whalebone whales, allied to the finbacks, but no ziphioid, or beaked, whales nor any true dolphins have been found.

The Destruction of the Fresh-water Fauna of Western Pennsylvania: Dr. ARNOLD E. ORTMANN, of Pittsburg.

The fresh-water fauna forms part of our natural resources. That it has been injured and partly destroyed by the advance of civilization is well known, but it is not realized how far the destruction has advanced. Since a number of fresh-water creatures are of economical value

(fishes, mussels), and since all creatures belonging to the ecological community of the fresh-water are mutually dependent upon each other, it is very desirable that the causes which lead to the destruction of fresh-water life should be removed.

These causes are: direct extermination by man; pollution of the streams; and river "improvements," as, for instance, the building of dams. The pollution of the water is the most important cause, and, in western Pennsylvania, it is chiefly the coal mining and the oil industries which have contributed to the deterioration and destruction of the fresh-water fauna.

The extent to which this contamination of the waters has been carried in western Pennsylvania was clearly laid down on a map.

The Stratigraphic Position of the Oolitic Iron-ore at Bloomsburg, Pa.: GILBERT VAN INGEN, of Princeton.

A study of the so-called "Clinton fossil iron ores" in the vicinity of Bloomsburg, Pa., shows that these oolitic areas are above the Shawangunk grit and conglomerate which is Lower Salina in age, and that they are certainly above the Lower Salina. They contain an extensive fauna and the paleontological evidence points to a Salina age, at least post-Clinton and post-Niagara.

A Mechanical Device for the Tabulation of the Sums of Numerous Variable Functions: Professor ERNEST W. BROWN, of New Haven.

On Certain Generalizations of the Problem of Three Bodies: President EDGAR ODELL LOVETT, of Houston, Texas.

Penrose's Graphical Method of Orbit Computation: Mr. ERIC DOOLITTLE, of Philadelphia.

The method shows how, when the exact position of a moving comet or planet among the stars has been observed on three or more nights, the path of the body can be determined and also the position which the body will occupy as viewed from the earth at any desired time. But little computation and no knowledge of higher mathematics is necessary in applying the method which well illustrates the principles of more intricate methods and also enables the position of the body in the sky to be predicted with sufficient accuracy to render it easily found in a telescope at any time.

On the Remarkable Changes in the Tail of Comet O. 1908 (Morehouse), and on a Theory to Account for these Changes: Professor E. E. BARNARD, of Yerkes Observatory, Williams Bay, Wis.

Professor Barnard exhibited a remarkable series of photographs made with the photographic telescopes at the observatory, showing changes that occurred in the tail of this comet which appear to indicate resistance to the passage of the body through space. In discussion of the paper it was suggested that this resistance might arise from clouds of meteoric dust, too fine to be visibly appreciable, but which might still be dense enough to offer a resistance that would account for the changes in the form of the tail of the comet that were shown by the photographs.

The Past History of the Earth as Inferred from the Mode of Formation of the Solar System: Dr. T. J. J. SEE, of U. S. Naval Observatory, Mare Island, Cal.

Linear Resistance between Two Parallel Conducting Cylinders: Professor A. E. KENNELLY, Harvard University, Cambridge, Mass.

The equipotential surfaces perpendicular to the lines of flow between two equally and oppositely charged parallel wires of very small radii are cylinders whose axes are in the plane of and parallel to the charged wires. If any of these cylinders were made conducting and the charge on the wire within transferred to it, the lines of flow and equipotential surfaces on the outside would remain the same. Hence the resistance between any two such cylinders can be expressed in terms of their radii and the distance between their centers. The equivalent linear resistance between two equal cylinders or of one cylinder and the medium plane may be simply expressed as a product of its circumference and a function of its radii and the distance of its center from the plane.

Vacuum Effects in Electrical Discharge around a Right Angle in a Wire: Professor FRANCIS E. NIPHER, of St. Louis.

On the Ruling of Diffraction Gratings: Professor ALBERT A. MICHELSON, University of Chicago, Ill.

The paper gave a brief statement of the development of the grating, mentioning the ingenious wire grating of Fraunhofer, the improvements of Rutherford, and the magnificent gratings of Rowland. These were sufficient in their day, but problems connected with more recent researches like the Zeeman effect and phenomena of that nature demanded a much greater resolving power. In this connection it was pointed out that the important fact was not so much the number of rulings per inch as the total number of rulings, and that this greater number of rulings necessi-

tated a correspondingly greater degree of regularity—an accumulated error of one ruling in the entire number being fatal.

The ruling engine now set up in the Ryerson Laboratory gives this necessary increase in perfection of ruling, so that the spectra are almost free from ghosts and those of the higher orders can be used. The resolving power is proportional to the product of the total number of rulings into the order. A photograph of a part of the Hg spectrum was shown, in which the distance between two of the lines was only one two-thousandths of the distance between the Na D lines, and it was evident that lines separated by only one half of this distance would be distinctly resolved.

This ruling engine is the result of seven years' work. The large ten-inch gratings are ruled on metal to save the cutting edge of the diamond, and weigh about thirty pounds. The greater part of this weight is supported by a float in mercury, only a small part pressing upon the ways. It is moved along the ways by a screw with a large head working by fine teeth in an automatically actuated worm. This screw was made as perfect as possible by long, careful grinding and the remaining errors which are of the order of the one millionth part of an inch are automatically compensated for by a slight tangential motion of the worm. This motion is a function of the position of the nut, determined empirically.

On an Adjustment for a Plane Grating Similar to Rowland's for the Concave Grating: Professor CARL BARUS, assisted by M. Barus, of Providence.

By using two slides, one symmetrically normal to the other, and observing on both sides of the point of intersection, it is shown that many of the errors are eliminated by the symmetrical adjustments in question. The slide carrying the grating may be provided with a focusing lens in front, or again behind it, if the means are at hand for actuating the slit, which is not sharply in focus throughout the spectrum at a given time, on the plane of the eye piece carried by the second slide. It is thus best to use both lenses conjointly, the latter as a collimator and the former as an objective of the telescope in connection with the eye piece. The authors show that a centimeter scale parallel to the eye piece slide, with a vernier reading to millimeters, is sufficient to measure the wave lengths of light to few Angström units, while the wave lengths are throughout strictly proportional to the displace-

ments along the scale. The errors of the three available methods and their counterparts are discussed in detail.

The Electrometer Method of Standardising the Coronas of Cloudy Condensation: Professor CARL BARUS, of Providence.

The author makes use of Thomson's method of measuring the charge of an electron in terms of the velocity of the ions and their number. The latter, however, are determined from the angular diameter of the coronas of cloudy condensation, produced in a cylindrical fog chamber under given conditions of rapid exhaustion. By providing the chamber with a charged axial aluminum tube closed within, and charged or not with sealed tubelets of radium acting through the aluminum walls in virtue of its beta and gamma rays, the fog chamber becomes an electrical condenser with a variable ionization. The electrical current passing from core to the shell of the cylindrical condenser may therefore be simultaneously measured by a sensitive electrometer. If it be assumed that negative ions only are caught in the fog chamber used and if the author's earlier and independent results are employed for stating the nucleation value of the coronas, the following data are typical for the enormous ionizations produced:

Total number of ions per cub. cm. = 1,700,000, 385,000, 135,000.

Corresponding value of ten thousand million times the electrical charge = 4.4, 3.6, 3.9 electrostatic units.

The author discusses the results critically and shows that the displacement of ions during exhaustion is the most serious source of discrepancy. Again that in a house in which a continuous lighting circuit terminates, it is absolutely essential to determine both the positive and negative current in the condenser separately, as they are liable to be widely different. On the other hand, the effect of gamma rays on the outside of the fog chamber and of conduction currents is almost negligible for a well-installed apparatus.

The Electrometric Measurement of the Voltair Potential Difference between Two Conductors of a Condenser containing a Highly Ionized Medium: Professor CARL BARUS, of Providence.

Solar Activity and Terrestrial Magnetic Disturbances: Dr. L. A. BAUER, of Washington.

This paper deals with the connections between the various manifestations of solar activity, e. g., sun-spots, and the so-called magnetic storms which at times affect compass needles simultaneously all over the earth by several degrees and even cause

serious interruption in telegraph and cable lines, and are usually accompanied by fine auroral displays. One of the most severe of these magnetic storms was that of October 30–November 1, 1903, which was violent enough to derange the mariner's compass at certain places by as much as 3° and even was said to have caused a temporary suspension of the electric car lines in Zürich, Switzerland. The effect from this particular storm lasted for fully two months after its apparent subsidence, the earth's magnetic condition being *below* normal until towards the close of the year (1903).

Renewed interest has been shown by the recent discoveries of Professor Hale, director of the Carnegie Solar Observatory at Mount Wilson, Cal., viz., that sun-spots are centers of violent cyclones and that they are accompanied by powerful magnetic fields. But however intensely magnetic these whirling cyclones may be, a simple calculation shows that they are far too distant to appreciably affect our most sensitive magnetic instruments.

Yet the various curves exhibited show indisputably that some relation exists between solar activity, as evidenced, for example, by sun-spots, calcium flocculi, solar eruptions, prominences, etc., and the earth's magnetic fluctuations. The variations in the solar and the terrestrial magnetic phenomena follow each other closely. One of the most important of the conclusions drawn is, that *an increase in sun-spot activity is accompanied by a decrease in the earth's magnetization, or that the magnetization superposed on the earth's magnetic field during solar outbreaks is opposite to that of the earth's own field.*

It appears questionable whether the earth's magnetism ever settles down precisely to its former condition after the occurrence of a magnetic storm.

The facts are not yet sufficient to draw a definite conclusion whether solar activity and magnetic storms stand to each other as cause and effect or whether they are both effects of the same cause. The indications are, that during a period of intense solar activity, in some as yet unknown manner, considerable fluctuations are caused to take place in the electric field that we know from various facts exists in the regions above us. These varying electric currents in turn affect the magnetic needles on the earth's surface.

On the Hevelian Halo: Professor CHARLES S. HASTINGS, of New Haven, Conn.

The paper reviewed the various kinds of halos that have been described and the explanations that have been offered in regard to their origin. It

had been assumed by writers on the subject that the snow crystals, which are in the form of plates or prisms, would fall with the plate or prism presenting the least resistance to the air. Thus, according to this idea, the hexagonal plates would fall edge on and the prism end on. This was shown to be incorrect and the contrary was the case, the plates and prisms could fall through the air with their longer dimensions horizontal. The plates would assume a horizontal position as well as the prisms. The halo was then caused by total internal reflection from the plates or prisms and not by surface reflection. Assuming these general positions for the long or short prisms (or plates) and total internal reflection the various types of halo that have been described could be explained, with the exception of the Hevelian halo. To explain this on the basis of total internal reflection it was necessary to assume pyramidal planes in the crystal of such an angle as to produce the 90 degree halo of this rare type.

The Effect of Temperature on the Absorption of Certain Solutions: Professor HARRY C. JONES, of Baltimore.

An account of experiments on the absorption spectra of certain solutions which Dr. Jones is carrying on under the auspices of the Carnegie Institution of Washington, D. C. Increase of temperature of the solution was found to alter the absorption spectra in the same way that they are changed by concentration of the solution.

The Specific Chemo-therapy of the Protozoal Diseases: Dr. SIMON FLEKNER, of the Rockefeller Institute for Medical Research, New York.

The Unsuspected Presence of Habit-forming Agents in Beverages and Medicines: Dr. LYMAN F. KEBLER, of Washington.

The paper considers the increased use of various habit-forming drugs. Attention is called to the fact that a large number of soft drinks contain not only a considerable amount of caffeine, but in many instances small quantities of cocaine. The presence of cocaine has also been found in a considerable number of agents intended for the treatment of the tobacco habit. The presence of the same pernicious drug has been revealed in medicine used in the treatment of hay fever, asthma and for relieving pain resulting from dentition in infancy. The presence of morphine, opium, chloral hydrate, heroin and codein, singly or combined, has also been found in many other medicines, particularly those intended for the treatment of epilepsy, rheumatism, asthma, gastric troubles and ailments of infancy and childhood.

SYMPOSIUM ON EARTHQUAKES

Introduction, Classification, Discussion of Volcanic Earthquakes, Description, with Illustrations, of the Charleston, S. C., and Kingston, Jamaica, Disasters: Professor EDMUND O. HOVEY, New York.

The Present Status and the Outlook of Seismic Geology: Professor WILLIAM H. HOBBS, of Ann Arbor, Mich.

Conditions Leading to Tectonic Earthquakes—Instruments used in the Study of Earthquakes—Suggestions for a National Seismological Bureau: Professor HARRY F. REID, of Baltimore.

Professor Hovey's paper served as an introduction to the subject. The ideas in regard to the cause of earthquakes were considered, especial attention being given to a discussion of volcanic earthquakes. Professor Hovey described the Charleston and Kingston earthquakes and illustrated his description by lantern slides. At the conclusion of his paper he exhibited a series of views of the Messina earthquake of December, 1908.

Professor W. H. Hobbs spoke of the manner in which the subject of seismology had been retarded by the publications of Robert Mallet, who advocated the idea that the shock originates at some point underground called the seismic focus or centrum, and from which center elastic waves are propagated in all directions. Professor Hobbs pointed out the fact that the "centrum" as determined by the method of Mallet was at best a line and practically had no existence. He explained the production of earthquakes by the shifting of segments of the crust along already existing fissures due to geotectonic movements, and insisted upon the tectonic origin of earthquakes. Volcanic activity and earthquake activity may be associated, as volcanoes are located along lines of fissure in the crust. Release of strain by shifting of the crust blocks, accompanied by earthquakes, as has been going on in the earthquake regions surrounding the Pacific Ocean in the last few years, probably produces in such a region an establishment of approximate equilibrium so that earthquakes may not be so severe for some time. The probability of earthquakes occurring in a given region may be tentatively predicted by a study of such crustal adjustment, but such predictions must be considered as tentative only. The upward or downward movement of the surface during earthquakes may be considerable, producing raised beaches, as has recently occurred in the Alaskan Islands. Along some coast lines the

evidence of such movement is to be seen in the raising of sea caves, and also the undercut portions of sea-cliffs, above the water level. As these movements involve many feet of elevation during an earthquake, perhaps the ideas of Lyell on the rate of changes of level of the land and sea may have to be modified.

Professor Harry Fielding Reid considered three phases of the subject: (a) conditions leading to tectonic earthquakes, (b) instruments used in the study of earthquakes, (c) suggestions for a national seismological bureau.

(a) The rocks have the properties of elastic substances and can only break after they have been deformed by the action of external forces. When they are strained beyond their strength a break occurs and the rocks return to an unstrained position, but it is only in the general neighborhood of the rupture that any distinct displacement takes place at the time of the earthquake.

(b) Earlier investigators attempted to obtain a "steady point"; that is, a point which would remain at rest when the earth vibrated under the earthquake disturbances. This, however, is impracticable. All earthquake instruments must have a proper period of vibration and when the disturbance affects them the resulting record is a combination of the movement of the earth and the movement of the instrument. When the period of vibration approaches that of the instrument, the latter has a very large swing and therefore the records unduly magnify special vibrations. This can be avoided by introducing strong damping. The different forms of instruments were briefly noticed.

(c) The work of a national bureau would be very varied. It would require the collection of data regarding all felt earthquakes, and a geological examination, in special cases, of the regions where earthquakes occur. The instrumental records from the whole country should also be collected and studied to throw light on the nature of the earth's interior, and to discover the centers of earthquake disturbances in the surrounding oceans. This would require the general cooperation of many departments of the government and could probably be best undertaken by the Smithsonian Institution.

At the conclusion of the discussion following the symposium Professor Hobbs presented the following resolutions, which were unanimously adopted:

WHEREAS: Earthquakes have been the cause of

great loss of life and property within the territory of the United States and its possessions, as well as other countries; and

WHEREAS: It is only through the scientific investigation of the phenomena that there is hope of discovering the laws which govern them, so as to predict their occurrences and to reduce the danger to life and property; and

WHEREAS: Such investigations can be successfully conducted only with the support of the general government, be it therefore

Resolved, That this society urge upon Congress the establishment of a national bureau of seismology, and suggest that this bureau be organized under the Smithsonian Institution with the active cooperation of the other scientific departments of the government, and that this bureau be charged with the following duties: (a) the collection of seismological data, (b) the establishment of observing stations, (c) the organization of an expeditionary corps for the investigation of special earthquakes and volcanic eruptions in any part of the world, (d) the study and investigation of special earthquake regions within the national domain, and

Resolved, That copies of these resolutions be transmitted to the president, the speaker of the house of representatives, to the president of the senate and to the secretary of the Smithsonian Institution.

The Evolution of the City of Rome from its Origin to the Gallic Catastrophe: Professor JESSE B. CARTER, of Rome, Italy.

An attempt to sketch in its outlines the development of the city of Rome from its origin to the Gallic catastrophe. The original people lived in little communities upon the hilltops, each community surrounded by a circular wall or stockade. The geological character of the campagna and its topography produced a number of elevations admirably adapted for such settlements. All of these little hilltop towns must have been very similar in population and customs and no one was probably a leader among them. Their consolidation into a city is assigned to the influence of an invasion by the Etruscans who conquered these hill towns, and enclosed them along with their intervening valleys with one wall. Some villages remained without the wall, as suburbs to be afterwards incorporated in the city; such were the Aventine region and the Campus Martius. The city had then outgrown its original dimensions and was no longer all within walls, which accounts for the ease with which it was captured by

the Gauls in 390 B.C. With the capture of the city by the Gauls Rome enters upon her period of inviolability for almost eight hundred years and the thought suggests itself irresistibly that the reputation for inviolability thus gained may have been a large factor in preserving her inviolate. Even in their early days the city began to be "that so holy spot, this very Rome."

On the Extent and Number of the Indo-European Peoples: Professor MAURICE BLOOMFIELD, of Baltimore.

The Burning Bush and the Origin of Judaism: Professor PAUL HAUPT, of Baltimore.

The Israelites probably never saw Egypt. The so-called Israelites who were in Egypt were the descendants of Esau, the Edomites. The burning bush was explained as the shrubbery on the heights of a volcano, lighted up at night by the glow of the incandescent lava. The story of the pillar of cloud by day and pillar of fire by night was not that it hung over the tabernacle but over Mount Sinai, the cloud of steam from the active volcano was the "pillar of cloud by day and the pillar of fire by night." The myths in regard to the destruction of Jericho and of Sodom and Gomorrah were attributed to the effect of earthquakes.

Magic and Religion: Professor EDWARD W. HOPKINS, of New Haven.

Milton's Confession of Faith: The Identity of Religious Belief between Milton and George Fox: ALDEN SAMPSON, of Haverford, Pa.

J. J. Rousseau, a Precursor of Modern Pragmatism: Professor ALBERT SCHNIZ, of Bryn Mawr, Pa.

At the Darwin commemorative meeting, after the presentation of the three addresses attention was called to the fact that there were two members of the American Philosophical Society still living in England who were friends of Charles Darwin—Sir Joseph Dalton Hooker and Dr. Alfred Russel Wallace—and on motion it was unanimously resolved that the society should cable to them its greetings and congratulations on the general acceptance of the views in the elaboration and promulgation of which they had taken such an effective part.

Early in the day a telegram was sent to Vice-president Simon Newcomb conveying to him the society's good wishes and greeting and their regret that he could not be present at the meeting.

The meeting was largely attended by members from various parts of the country and was regarded as most successful both from the point of

view of the quality of the papers read and the number and broadly representative character of the members who took part in it.

The sessions closed with a dinner at the Bellevue-Stratford, on Saturday evening, April 24, at which about one hundred members were present and at which the speakers were: President Patton, of Princeton; the British Ambassador, Mr. Bryce; President Pritchett, of the Carnegie Foundation; President-elect Lowell, of Harvard, and President Keen, of the American Philosophical Society.

The annual election of members held at the executive session on Saturday, April 24, resulted in the election of the following candidates:

Residents of the United States.—Louis A. Bauer, Ph.D. (Berlin), Washington, D. C.; Marston Taylor Bogert, New York; Hermon Carey Bumpus, Ph.D., New York City; Alexis Carrel, M.D., New York City; Edwin Brant Frost, Williams Bay, Wis.; Robert Almer Harper, Ph.D., Madison, Wis.; William Herbert Hobbs, Ph.D., Ann Arbor, Mich.; A. V. Williams Jackson, Ph.D., LL.D., Yonkers, N. Y.; John Frederick Lewis, Philadelphia; Abbott Lawrence Lowell, Boston, Mass.; William Romaine Newbold, Ph.D., Philadelphia; Charles Bingham Penrose, M.D., Ph.D., Philadelphia; William Howard Taft, Washington; Charles Richard Van Hise, M.S., LL.D., Madison, Wis.; Victor Clarence Vaughan, M.D., Sc.D., LL.D., Ann Arbor, Mich.

Foreign Residents.—Francis Darwin, M.A., F.R.S., Cambridge, Eng.; Hermann Diels, Ph.D., Berlin; Emil Fischer, Ph.D., M.D., Berlin; Friedrich Kohlrausch, Ph.D., Marburg; Wilhelm F. Pfaffer, Ph.D., Leipzig.

SOCIETIES AND ACADEMIES

THE ACADEMY OF SCIENCE OF ST. LOUIS

On the evening of Monday, March 1, the regular meeting of the Academy of Science of St. Louis was held at the Academy Building, the feature of the program being a paper, read by Mr. Julius Hurter. The subject of the discourse, which had been compiled by Mr. Hurter and Mr. John K. Strecker, Jr., was "The Amphibians and Reptiles of Arkansas."

After stating that up to the present time definite records are obtainable from only 15 of the 75 counties of Arkansas, Mr. Hurter recorded the facts that 100 species of reptiles and amphibians have been reported from Arkansas, and 90 from Missouri. Thirteen of the Arkansas species are not known to occur in Missouri, and nineteen are not found in eastern Texas. Most of the species

are eastern and southeastern forms which find their western limit in Arkansas and the eastern half of Louisiana. Another interesting fact brought out was this—that of the 71 species occurring in both Arkansas and the eastern half of Texas, 63 are also found in the state of Missouri. Mr. Hurter showed numerous specimens in illustration of his paper, and also the blind salamanders of the world: *Proteus anguinus* (European blind salamander), *Typhlotriton epelæus* (Missouri) and *Typhlomolge rathbuni* (Texas).

At this meeting, on proper motion, duly seconded and unanimously carried, the following memorial was adopted as expressing the views of the academy; and copies were ordered sent to the speaker of the house of representatives, the president of the senate, and the gentlemen who represent Missouri in both branches of the present Congress:

"The Academy of Science of Saint Louis, an organization equally interested in the preservation and the proper and consistent utilization of the gifts of nature, respectfully urges on the Congress of the United States the desirability of promptly passing the House Joint Resolution now under consideration as a means of continuing the provisions of the Burton Bill, limiting the diversion of water from Niagara Falls, until equally effective but more permanent protection of the Falls shall be secured by adequate legislative or executive action."

THE program of the meeting of the Academy of Science of St. Louis which occurred on March 15 was a paper by Mr. Otto Widmann on "The Birds of the Missouri Botanical Garden." In twenty visits to the garden during the summer of 1908, Mr. Widmann noted forty species of birds breeding there, and six species which were more or less regular visitors from near-by breeding grounds. And, besides these, there were scores of transient visitants during the migratory seasons. The breeders are the bob-white, mourning-dove, screech owl, yellow-billed cuckoo, black-billed cuckoo, red-headed woodpecker, northern flicker, chimney swift, kingbird, great crested flycatcher, wood pewee, Traill's flycatcher, blue jay, crow, cowbird, red-winged blackbird, meadow lark, orchard oriole, Baltimore oriole, bronzed grackle, goldfinch, English sparrow, English tree sparrow, chipping sparrow, song sparrow, towhee, cardinal, rose-breasted grosbeak, indigo bunting, warbling vireo, Bell's vireo, yellow warbler, yellow-throat, yellow-breasted chat, mockingbird, catbird, brown thrasher, house wren, wood thrush and robin.

Of the whole bird population of the garden, only four species are permanent residents. And these are the bob-white, flicker, mockingbird and red-bird. The regular visitors are the sparrow-hawk, king-fisher, night-hawk, humming-bird, purple-martin and cedar waxwing. The numerous hedges of dense shrubbery harbor Bell's vireo, yellow warbler, Maryland yellow-throat, chat, Traill's flycatcher and the indigo bunting. In the arboretum are found the crested flycatcher, wood pewee, wood thrush, cuckoos and the gentle mourning doves. The meadow has attracted quails and meadow-larks. The ripening mulberries are an attraction for flocks of cedar birds in early June, and the many beautiful flowers charm numberless hummingbirds later in the summer.

Thirty or more species of birds were on exhibition to illustrate Mr. Widmann's paper.

At this meeting the following resolution was adopted: "On the recommendation of its entomological section, and with approval of its council, the Academy of Science of St. Louis, on duly seconded and passed motion at its regular meeting of the fifteenth of March, 1909, respectfully urges on the members of the General Assembly of the State of Missouri, the importance of passing House Bill No. 575, and Senate Bill No. 197, providing the adequate inspection of nursery stock. At the present moment the entire orchard and nursery industry of the state is imperiled by a threatened introduction of the dreaded brown-tail moth, in the bare restriction of which New England has for years waged a costly warfare. Nothing but adequately planned and efficiently administered state inspection can protect this important industry of Missouri in the present or in future crises."

On April 5, the Academy of Science of St. Louis met to hear a paper presented by Prof. Whinthrop Holt Chenery, of Washington University, on "The relation of the Physiography of the Iberian Peninsula to the Development of the Spanish and Portuguese Peoples." Mr. Chenery considered the distinguishing features of the peninsula—topographic, geological and climatic—and their significance as determining factors in the historical evolution of the peoples. In particular he showed that the chief occupations of the inhabitants, ever since prehistoric times, have been determined by the physical character of the country; and that the long-continued prevalence of these occupations has produced widely divergent types of people.

The lecture was fully illustrated, and insistence was laid upon the importance of the study of

physical environment to the understanding of the Spanish-Portuguese history.

W. E. McCourt,
Recording Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 664th meeting was held April 10, 1909, Vice-President Wead in the chair. Two papers were read.

An Approximate Method of Analysis of E.M.F. Waves: P. C. AGNEW.

A knowledge of the impurities present in the E.M.F. wave given by a generator is required in many engineering and physical problems. While a large number of methods have been devised for the analysis of such E.M.F. waves, those methods which give quantitative results require highly specialized and expensive apparatus. The experiments described were undertaken to determine if it is possible to obtain reliable results by the use of condensers and portable indicating instruments only.

For the same effective voltage, a distorted wave will pass more current into a condenser than will a pure sine wave. We ought, then, to be able to use this fact to determine the amount of impurities present in a given wave. Obviously a greater accuracy can be attained if we make the analysis depend on bridge values of resistance, inductance and capacity, and so make it independent of the absolute calibrations of the voltmeter and ammeter used. This may be accomplished by replacing the condenser by a resistance and adjusting to give the same readings of ammeter and voltmeter. We may consider that each component of voltage, e_n , causes the corresponding component of current, i_n , to flow. The square of the effective value of current indicated by the ammeter is equal to the sum of the squares of the components. If in the case of the presence of the n th harmonic only, C represents the capacity, L the inductance, r the resistance, and if p is 2π times the frequency,

$$I^2 = \frac{e_1^2}{r^2 + (pL - 1/pC)^2} + \frac{e_n^2}{r^2 + (npL - 1/npC)^2}.$$

Now on removing the condenser and increasing the resistance to R , we have, for the same readings of voltmeter and ammeter,

$$I^2 = \frac{e_1^2}{R^2 + p^2L^2} + \frac{e_n^2}{R^2 + n^2p^2L^2}.$$

From these relations, we get the ratio of the harmonic to the fundamental E.M.F.,

$$\frac{c_n}{c_1} = \frac{\sqrt{1/a_2 - 1/a_1}}{\sqrt{1/a_2 - 1/a_4}}$$

where a_1, a_2, a_3, a_4 have been written for the four impedances in the denominators above.

While theoretically the method may be extended to any number of harmonics, it is practically limited to two by the accuracy of readings and by the labor of computation. Experiments in the analysis of waves built up by combining the E.M.F.'s of different machines, and also by the analysis of E.M.F. waves of single generators, show that the method is capable of an accuracy of two or three per cent. of the fundamental.

The method has the disadvantages of giving no information of the phase relations, and of not readily lending itself to the analysis of current waves. The advantages are that it requires no special apparatus; direct access to the generator, or the use of synchronous motor, is not necessary; and the accuracy is better than that of an oscillograph, though not equal to that of a curve tracer.

The Accurate Analysis of Alternating Current Waves: F. W. GROVER.

With the rapid development, in recent years, of methods and apparatus for the tracing of alternating current waves, the question of the convenient analysis of the curves obtained has become increasingly important. Although the well-known method of Fourier is the most direct and accurate, its employment seems to be quite generally regarded as too laborious for general use. This is evidenced by the appearance of a number of graphical and planimetric methods, among which may be mentioned those of Clifford, Fischer-Hinnen, and Houston and Kennelly. All these modes of procedure, however, labor under the disadvantage, inherent in all graphical methods, of inaccuracy where small quantities are involved, without any saving of time over that required to derive the values of an equal number of harmonics by the Fourier analysis if the calculation be suitably arranged.

In 1897 Rosa simplified the calculation by the use of a table from which the required products of the ordinates by the sines of the angles could be taken directly from a table. Using this, all the odd harmonics up to and including the 15th can be obtained in a little over an hour.

S. P. Thompson¹ showed that the work could be still further shortened, (1) by grouping together those ordinates which are to be multiplied by the sines of the same angle, and (2) by dividing the

¹ *Electrician*, May 5, 1905.

half wave into an even number n of equal parts, when the products divide themselves into complementary groups, so that the k th and $(n - k)$ th harmonics are found, respectively, by adding and subtracting the sums of two groups of products. He gave the complete scheme of calculation for the two cases, $n = 6$ and $n = 12$. The whole analysis in the former case may be carried through in ten minutes or even less.

The electromotive force waves of alternators with slotted armatures, however, often contain the higher harmonics to an appreciable extent, and these may greatly distort the form of the current wave in circuits containing capacity. The speaker has therefore developed the scheme of calculation for the case of 18 ordinates and has prepared a table to facilitate the multiplications. Such a table need include the ordinates up to 100 only, the fractional parts being found from the same table by shifting the decimal point. Using this method the amplitudes of all the harmonics up to and including the 17th may be determined in about half an hour with an accuracy and ease not attainable by any graphical method.

R. L. FARIS,
Secretary

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 458th meeting was held April 3, 1900, with President Palmer in the chair. Lantern slides made by a novel application of well-known methods were shown upon the screen by Mr. A. A. Doolittle. The silver is thoroughly removed from plates, leaving only the gelatin film; from old, unused or undeveloped plates by the usual hypo bath, and from poor or waste negatives by the reducing process with ferri-cyanide. On immersing the thoroughly washed plate in blue print solution for five minutes and subsequent drying in the dark, they may be printed upon by contact with negatives in the usual manner. They give clear high lights and contrasting effects, desirable qualities in lantern slides or transparencies. The color is a pleasing semi-translucent blue. The method is simple and can be used by the inexperienced. Beautiful window transparencies are similarly made.

The following communications were presented: *Classification of the True Fishes:* THEODORE GILL.

The speaker restricted the class Pisces to the true fishes or Teleostomes, as he had done since 1873. Two of the best zoologists of Europe (Hübner, of Holland, and Regan, of the British Museum) have recently come to the same con-

clusion. Regan has also recently (January, 1909) published on "The Classification of Teleostean Fishes" and admitted four subclasses of Teleostomes and 31 orders of Teleosts. The four subclasses are the same as four of those recognized by the speaker in 1896; a fifth then admitted in deference to the general sentiment at that time (Hyoganoidea) may now be suppressed. Remarks were made on the contrast between the orders recognized till past the middle of the last century and those now admitted by Mr. Regan and the speaker. Praise was accorded to Regan for his work, but the speaker was disposed to dissent from him as to certain groups and presented the following list of orders. Those named without synonyms are the same as Mr. Regan's; the synonyms added after many are the names given by Regan. It was especially insisted upon that the list was only provisional and tentative and that no significance need be attached to the exact position or sequence of some of the orders. The author is now employed in further studies of the osteology.

Our knowledge of the extinct types is in such an unsatisfactory condition that the present list is restricted to the living forms.

Class Pisces

Subclass Dipnoi or Dipneusti.

Order Sirenoidei.

Subclass Crossopterygii.

Order Semiopteri or Cladistia.

Subclass Chondroganoidei.

Order Chondrostei.

Order Selachostomi.

Subclass Teleostei.

Order Rhomboganoidei or Ginglymodi.

Order Cycloganoidei or Protopterygii.

Order Malacopterygii or Isospondyli.

Order Inioi.

Order Scyphophori (S. O. Mormyroidei).

Order Plectospondyli (S. O. Cyprinoidei).

Order Nematognathi (S. O. Siluroidei).

Order Symbranchii.

Order Carencheli.

Order Apodes.

Order Lyomeri.

Order Oplisthomi.

Order Heteromi.

Order Lyopomi (Heteromi pt.).

Order Xenomi (S. O. Dalioidei).

Order Haplomi (Microcyprini).

Order Syntognathi.

Order Salmoperes.

Order Peresoces.

The Guano-birds of Peru: ROBERT E. COKER.
(Illustrated with lantern slides.)

The chief guano-producing birds in order of importance are—a cormorant (*Phalacrocorax bougainvillei* Less.), the pelican (*Pelecanus molinae* (Molina) Gr.) and a gannet (*Sula variegata* Tach.). A small petrel (*Halodroma garnoti* Less.) has some significance, and, if earlier accounts are accepted, it was formerly much more abundant and important. The penguin (*Spheniscus humboldti* Meyen) was reputed to be commercially important a few decades ago. Other interesting birds were observed on and near the islands.

The pelican has suffered most from the disturbance incident to the extraction of guano from the rookeries. The bird has been practically eliminated from the small islands of the southern region, but still breeds in great numbers on the larger islands of the north. A colony of pelicans, between twenty and forty thousand in number, was observed on the Lobos de Afuera Islands. Since 1906 the Peruvian government has enforced a "closed" season of five months annually, but it is expected that a more adequate plan of rotation will be adopted, so that the birds on certain islands may be undisturbed for periods of years. In partial adoption of this plan, the South Island of the Chincha group has been kept "closed" for nearly three years. It is estimated that, by the expiration of the three years, a deposit of twenty thousand tons will have accumulated upon this island.

THE 459th meeting was held April 17, 1909, in Hubbard Memorial Hall, with President Palmer in the chair. The evening was devoted to a lecture by Mr. Charles Sheldon, of New York, on "Experiences with Big Game in the Mt. McKinley Region, Alaska," illustrated by a large number of stereopticon views of the country and of mountain sheep, caribou, moose, lynx, bear and ptarmigan.

RACE PROBLEMS IN AMERICA¹

THE development of the American nation through amalgamation of diverse European nationalities and the ever-increasing heterogeneity of the component elements of four people have called attention to the anthropological and biological problems involved in this process.

I propose to discuss here these problems with a view of making clear the hypothetical character of many of the generally accepted assumptions. It will be our object to attempt a formulation of the problems, and to outline certain directions of inquiry, that promise a solution of the questions involved, that, at the present time, can not be answered with scientific accuracy. It is disappointing that we have to accept this critical attitude, because the events of our daily life bring before our eyes constantly the grave issues that are based on the presence of distinct types of man in our country, and on the continued influx of heterogeneous nationalities from Europe. Under the pressure of these events, we seem to be called upon to formulate definite answers to questions that require the most painstaking and unbiased investigation. The more urgent the demand for final conclusions, the more needed is a critical examination of the phenomena and of the available methods of solution.

Let us first represent to our minds the facts relating to the origins of our nation. When British immigrants first flocked to the Atlantic coast of North America, they found a continent inhabited by Indians. The population of the country was thin,

¹Address of the vice-president and chairman of Section H, American Association for the Advancement of Science, Baltimore, 1908.

and vanished comparatively rapidly before the influx of the more numerous Europeans. The settlement of the Dutch on the Hudson, of the Germans in Pennsylvania, not to speak of other nationalities, is familiar to all of us. We know that the foundations of our modern state were laid by Spaniards in the Southwest, by French in the Mississippi Basin and in the region of the Great Lakes, but that the British immigration far outnumbered that of other nationalities. In the composition of our people, the indigenous element has never played an important rôle, except for very short periods. In regions where the settlement progressed for a long time entirely by the immigration of unmarried males of the white race, families of mixed blood have been of some importance during the period of gradual development, but they have never become sufficiently numerous in any populous part of the United States to be considered as an important element in our population. Without any doubt, Indian blood flows in the veins of quite a number of our people, but the proportion is so insignificant that it may well be disregarded.

Much more important has been the introduction of the negro, whose numbers have increased many fold so that they form now about one eighth of our whole nation. For a certain length of time the immigration of Asiatic nations seemed likely to become of importance in the development of our country, but the political events of recent years have tended to decrease their immediate importance considerably; although we do not venture to predict that the relation of Asiatics and white Americans may not become a most important problem in the future. These facts, however, are familiar to all of us and stand out clearly to our minds.

More recent is the problem of the immigration of people representing all the na-

tionalities of Europe, western Asia and northern Africa. While until late in the second half of the nineteenth century the immigrants consisted almost entirely of people of northwestern Europe, natives of Great Britain, Scandinavia, Germany, Switzerland, Holland, Belgium and France, the composition of the immigrant masses has changed completely since that time. With the economic development of Germany, German immigration has dwindled down; while at the same time Italians, the various Slavic peoples of Austria, Russia and the Balkan Peninsula, Hungarians, Roumanians, east European Hebrews, not to mention the numerous other nationalities, have arrived in ever-increasing numbers. There is no doubt that these people of eastern and southern Europe represent a physical type distinct from the physical type of northwestern Europe; and it is clear, even to the most casual observer, that their present social standards differ fundamentally from our own. Since the number of new arrivals may be counted in normal years by hundreds of thousands, the question may well be asked, What will be the result of this influx of types distinct from our own, if it is to continue for a considerable length of time?

It is often claimed that the phenomenon of mixture presented in the United States is unique; that a similar intermixture has never occurred before in the world's history; and that our nation is destined to become what some writers choose to term a "mongrel" nation in a sense that has never been equaled anywhere.

When we try to analyze the phenomena in greater detail, and in the light of our knowledge of conditions in Europe as well as in other continents, this view does not seem to me tenable. In speaking of European types, we are accustomed to consider them as, comparatively speaking, pure stocks. It is easy to show that this view

is erroneous. It is only necessary to look at a map illustrating the racial types of any European country—like Italy, for instance—to see that local divergence is the characteristic feature, uniformity of type the exception. Thus Dr. Ridolfo Livi, in his fundamental investigations on the anthropology of Italy, has shown that the types of the extreme north and of the extreme south are quite distinct—the former tall, short-headed, with a considerable sprinkling of blond and blue-eyed individuals; the latter short, long-headed and remarkably dark. The transition from one type to the other is, on the whole, quite gradual, but, like isolated islands, distinct types occur here and there. The region of Lucca in Tuscany and the district of Naples are examples of this kind, which may be explained as due to the survival of an older stock, to the intrusion of new types, or to a peculiar influence of environment.

Historical evidence is quite in accord with the results derived from the investigation of the distribution of modern types. In the earliest times we find on the peninsula of Italy groups of heterogeneous people, the linguistic relationships of many of which have remained obscure up to the present time. From the earliest prehistoric times on, we see wave after wave of people invading Italy from the north. Very early Greeks settled in the greater part of southern Italy and Phœnician influence was well established on the west coast of the peninsula. A lively intercourse existed between Italy and northern Africa. Slaves of Berber blood were imported and have left their traces. Slave trade continued to bring new blood into the country until quite recent times, and Livi believes that he can trace the type of Crimean slaves who were introduced late in the Middle Ages in the region of Venice. In the course of the centuries, the migra-

tions of Celtic and Teutonic tribes, the conquests of the Normans, the contact with Africa, have added their share to the mixture of people on the Italian peninsula.

The fates of other parts of Europe were no less diversified. The Pyrenean Peninsula, which at present seems to be one of the most isolated parts of Europe, had a most checkered history. The earliest inhabitants of whom we know were presumably related to the Basques of the Pyrenees. These were subjected to Oriental influences in the Pre-Mycenæan period, to Punic influences, to Celtic invasions, Roman colonization, Teutonic invasions, the Moorish conquest, and later on to the peculiar selective process that accompanied the driving-out of the Moors and the Jews.

England was not exempt from vicissitudes of this kind. It seems plausible that at a very early period the type which is now found principally in Wales and in some parts of Ireland occupied the greater portion of the islands. It was swamped by successive waves of Celtic, Roman and Anglo-Saxon migration. Thus we find change everywhere.

The history of the migrations of the Goths, the invasions of the Huns, who in the short interval of one century moved their habitations from the borders of China into the very center of Europe, are proofs of the enormous changes in population that have taken place in early times.

Slow colonization has also brought about fundamental changes in blood as well as in diffusion of languages and cultures. Perhaps the most striking recent example of this change is presented by the gradual Germanization of the region east of the Elbe River, where, after the Teutonic migrations, people speaking Slavic languages had settled. The gradual absorption of Celtic communities, of the Basque, in ancient times the great Roman colonization,

and later the Arab conquest of north Africa, are examples of similar processes.

Intermixture in early times was not by any means confined to peoples which, although diverse in language and culture, were of fairly uniform type. On the contrary, the most diverse types of southern Europe, northern Europe, eastern Europe and western Europe, not to mention the elements which poured into Europe from Asia and Africa, have been participants in this long-continued intermixture.

There is, however, one fundamental difference in regard to the early European migrations and the modern trans-Atlantic migration. On the whole, the former took place at a period when the density of population was, comparatively speaking, small. There is no doubt that the number of individuals concerned in the formation of the modern types of Great Britain were comparatively few as compared with the millions who come together to form a new nation in the United States; and it is obvious that the process of amalgamation which takes place in communities that must be counted by millions differs in character from the process of amalgamation that takes place in communities that may be counted by thousands. Setting aside social barriers, which in early times as well as now undoubtedly tended to keep intermingling peoples separate, it would seem that in the more populous communities of modern times a greater permanence of the single combining elements might occur, owing to their larger numbers, which make the opportunities for segregation more favorable.

Among the smaller communities the process of amalgamation must have been an exceedingly rapid one. After the social distinctions have once been obliterated, pure descendants of one of the component types decrease greatly in number, and the fourth generation of a people consisting

originally of distinct elements will be almost homogeneous. I shall revert to this phenomenon later on.

It might be objected to this point of view, that the very diversity of local types in Europe proves the homogeneity of race types—as, for instance, of the north-western European type, the Mediterranean type, the east European type, or the Alpine type; but it must be remembered that we have historical proof of the process of mixture, and that the relative number of component elements is sufficient to account for the present conditions.

I think we may dismiss the assumption of the existence of a pure type in any part of Europe, and of a process of mongrelization in America different from anything that has taken place for thousands of years in Europe. Neither are we right in assuming that the phenomenon is one of a more rapid intermixture than the one prevailing in olden times. The difference is based essentially in the masses of individuals concerned in the process.

If we confine our consideration for the present to the intermixture of European types in America, I think it will be clear, from what has been said before, that the concern that is felt by many in regard to the continuance of racial purity of our nation is to a great extent imaginary. The history of Europe proves that there has been no racial purity anywhere for exceedingly long periods, neither has the continued intermixture of European types shown any degrading effect upon any of the European nationalities. It would be just as easy to prove that those nations that have been least disturbed have lacked the stimulus to further advance and have passed through periods of quiescence. The history of Spain might be interpreted as an instance of an occurrence of this kind.

The question as to the actual effects of intermixture will not, however, be an-

answered by a generalized historical treatment such as we have attempted here. The advocates of the theory of a degradation of type by the influx of so-called "lower" types will not be silenced by reference to earlier mixtures in Europe, the course of which can no longer be traced in actual detail for we do not know to what extent actual intermarriages have taken place, and what the development of families of mixed descent as compared with those of pure descent has been. It seems necessary that the problem should be approached from a biological standpoint. It seemed well, however, to gain first a clearer view of the historical relations of our problem. A knowledge of the events of the past tends to lay our apprehensions, that make the problem exciting, and which for this reason fill the observer with a strong bias for the results which he fears or desires.

Two questions stand out prominently in the study of the physical characteristics of the immigrant population. The first is the question of the influence of selection and environment in the migration from Europe to America. The second is the question of the influence of intermixture. A beginning of a thorough study of the former question was made as early as the time of the civil war, when Gould and Baxter, in their statistics of the enlisted soldiers, proved that the immigrant representatives of European nations were always better developed than the corresponding people in Europe. It has not been possible, up to the present time, to learn whether this difference is due to better development here or to a process of selection, by which the weaker elements are eliminated before leaving their home country. It would be easy to ascertain the facts by an investigation of the arriving immigrants. That there is good reason to suppose that more favorable social surroundings in the United States have much

to do with the better development of the immigrants is proved by the anthropometrical statistics collected by Bowditch in Boston and by Peckham in Milwaukee, who found that the children growing up in America are better developed than European children. Although much additional material has been collected on the old lines, the fundamental questions which are involved in this investigation have never received adequate attention. Statistics which I had occasion to collect recently seem to show that the development of children of immigrants is the better the longer their parents have been in the United States. I presume this merely suggests that the economic well-being of the immigrants increases, on the whole, with the length of their stay here, and that the corresponding better nutrition of the children results in better physical development. Whether, however, the whole change can be explained adequately in this manner is open to doubt. It is quite possible that the type may undergo certain changes due to environment.

In how far types must be considered as stable is a question in regard to which there is still considerable diversity of opinion. Investigators like Kollmann maintain the absolute stability of the types now existing; while, on the other hand, indications are not absent which suggest a changeability of types, at least in certain respects. It would seem that stature may be considerably influenced by long-continued more or less favorable environment. There are investigators who maintain that the more or less energetic use of the jaws may influence the form of the head, owing to the pressure brought about by the muscles, which tend to compress the skull laterally. On the other hand, we have very clear evidence that features, like the form of the head, the form of the face and stature, are inherited from generation to

generation with great persistence. As long as these questions are still so far from being settled, it seems necessary to take into consideration the possibility of a change of type in the immigrants, due to the new surroundings in which they have been placed. Some anthropologists in America have even gone so far as to claim that the geographical environment affects the European in such a way that he begins to resemble the Indian type. I have failed to find, so far, even a trace of evidence on which this opinion can be based.

The only indication that I can offer which might suggest an influence of environment is an observation which I made a number of years ago in Massachusetts, where I found that the variability of type was remarkably low, considering the mixed composition of the population—a variability which is less than the corresponding values obtained in Europe. But a sporadic observation of such a character is, of course, entirely insufficient to solve a problem of this magnitude. It would seem to my mind that one of the most important and fundamental investigations that have to be made in regard to the question of the biological assimilation of immigrants is a thorough discussion of the sameness or change of type of the second and third generations.

It has often been observed that the local types which have developed in America show a considerable amount of individualization. Some of this may very well be due to the influence of environment. It might be, for instance, that the tallness of the people of Kentucky is due to the lime-water of that area. This would be in accord with the observations made by Rose in Gotha, who found that the stature in that city had changed with the introduction of hard water. It will certainly be possible to carry through this inquiry among a people like the Italians or Swedes,

where the anthropometrical conditions of the home country are fairly well known, while for many other nationalities parallel inquiries in Europe and in America would be necessary. Even if, by extended inquiries into the physical characteristics of the descendants of immigrants, the modifications of their type should become well known, the problem would still remain. In how far do these types increase in a pure state after their migration, in how far do they tend to become extinct, and what tendency they have to mix with the rest of the population. It seems best to defer a discussion of this question until after consideration of the influence of race intermixture.

Here we may consider again the physical effect of intermixture and the propagation of mixed types independently. I regret to say that the available information in regard to this point is, if anything, more meager than that relating to the modification of types after their migration into this country. The fundamental question that must be asked is, whether the mixture of two distinct types of man tends to produce an intermediate homogeneous type in which certain of the characteristics of the parents appear blended, or whether the resultant tends to exhibit reversion to the parental types. This reversion may again be twofold. We may either find a complete reversion to one of the component parental types, or we may find a mixture of traits, some resembling the one parent, some the other parent. Obviously this question is most intimately related to the whole study of Mendelian inheritance, which occupies such a prominent place in the work of modern biologists. So far, the results obtained from a study of human types are few in number. I believe the earliest observation in regard to this subject was made by Felix von Luschan, who found as early as 1884 that the inhabitants of the south coast of

Asia Minor, who are the descendants of intermarriages between a short-headed type of the central parts of Asia Minor and of the long-headed south coast type—a mixture which has continued for thousands of years—show clear evidence of alternating inheritance. In 1895 I was able to show (utilizing fairly extended observations) that the mixed blood resulting from unions of American Indians and whites shows, in regard to certain traits, a clear tendency to reversion to either parental type; while in other respects (for instance, in stature) new characteristics seem to develop. A recent inquiry into heredity among east European Jews shows that here also the children show a tendency to revert either to the father's or to the mother's type. This result is interesting, because it bears upon unions inside of a fairly uniform type of man. Other observations relate to the inheritance of abnormal traits, all of which seem to suggest, if not true Mendelism, at least the occurrence of alternating inheritance. However, the observations on mixtures of Indian and white have shown that while alternating inheritance may be found in regard to such traits as the form of the head and face, the development of the bulk of the body follows different laws. Notwithstanding these observations, the whole problem of the effects of race intermixture upon the various characteristic traits of human types is entirely unsolved.

It is not too much to say that the whole work in this field remains to be done. We do not know what weight to give to the small differences of types such as are found in Europe, and whether these differences are sufficiently great to be considered important as compared with the differences between individuals of the same geographical type but belonging to opposite ends of the local series. We must not forget that the people of Europe in each locality are

very variable, and that we may find (for instance, in Scotland) considerable numbers of individuals who will differ from one another more than do the average individuals of, let me say, Scotland and southern Italy. The question of the effects of intermixture of types can, therefore, not be treated entirely separately from the question of intermarriages among people belonging to the same locality. And it is worth considering whether the remoteness of blood relationship in different parts of Europe, as compared to the closer blood relationship inside of a narrow territory, may not outweigh all the influences of the differences of geographical types. The whole question seems to be most complex, and worthy of the most detailed and thorough study; but I do not venture to predict the anatomical and physiological effects of intermixture without a most painstaking investigation, which has not been made up to this time.

Considering our lack of knowledge of the most elementary facts that determine the outcome of these processes, I feel that it behooves us to be most cautious in our reasoning, and particularly to refrain from all sensational formulations of the problem, that are liable to add to the prevalent lack of calmness in its consideration; the more so since the answer to these questions concerns the welfare of millions of people.

The problem is one in regard to which speculation is as easy as accurate studies are difficult. Basing our arguments on ill-fitting analogies with the animal and plant world, we may speculate on the effects of intermixture upon the development of new types—as though the mixture that is taking place in America were in any sense, except a sociological one, different from the mixtures that have taken place in Europe for thousands of years; looking for a general degradation, for re-

version to remote ancestral types, or towards the evolution of a new ideal type—as fancy or personal inclination may impel us. We may enlarge on the danger of the impending submergence of the northwest European type, or glory in the prospect of its dominance over all others. Would it not be a safer course to investigate the truth or fallacy of each theory rather than excite the public mind by indulgence in the fancies of our speculation. That these are an important adjunct in the attainment of truth, I do not deny; but they must not be promulgated before they have been subjected to a searching analysis, lest the credulous public mistake fancy for truth.

If I am not in a position to predict what the effect of mixture of distinct types may be, I feel confident that this important problem may be solved, if it is taken up with sufficient energy and on a sufficiently large scale. An investigation of the anthropological data of people of distinct types—taking into consideration the similarities and dissimilarities of parents and children, the rapidity and final result of the physical and mental development of children, their vitality, the fertility of marriages of different types and in different social strata—such an investigation is bound to give us information which will allow us to answer these important questions definitely and conclusively.

The final result of race mixture will necessarily depend upon the fertility of the present native population and of the newer immigrants. It has been pointed out repeatedly that the birth-rate of Americans has declined with great rapidity, and that in the second and third generations of immigrants the same decline makes itself felt. It will therefore be important to know what the relation of fertility of different types may be.

If the fertility of foreigners continues high without a corresponding higher death-

rate of children, we may anticipate a gradual increase of the physical influence of the more fertile type. The immigration of the divergent types of southern and eastern Europe is, however, so recent, that this question can not be answered until at least twenty years more have elapsed.

No less important than the fertility of each immigrant type by itself is the question, in how far they tend to intermarry. The data presented in our census reports do not give a clear insight into this tendency among various nationalities. The difficulties of collecting significant statistics on the problem are very great. They appear particularly clear in the case of Italians. Married men from Italy come to the United States, earn some money, and go back to rejoin their families. They may come again, and, when conditions are propitious, they may finally send for their families to follow them. Thus we find among the Italian immigrants very large numbers who were married before they came here. It seems almost impossible to separate the contingent of couples married before their arrival here from those married after their arrival, and the chief point of interest to us lies in the intermarriages of children born in this country. It is natural that in large cities, where nationalities separate in various quarters, a great amount of cohesion should continue for some time; but it seems likely that intermarriages between descendants of foreign nationalities are much more common than the census figures would make it appear. Our experience with Americans whose grandparents immigrated into this country is, on the whole, that most social traces of their descent have disappeared, and that many do not even know to what nationalities their grandparents belonged. It might be expected—particularly in Western communities, where a rapid change of location

is common—that this would result in a rapid mixture of the descendants of various nationalities. This inquiry, which it is quite feasible to carry out in detail, seems indispensable for a clear understanding of the situation.

It is somewhat difficult to realize how rapidly intermixture of distinct types takes place, if the choice of mates is left entirely to accident. I have made this calculation; and I find that in a population in which two types intermingle, and in which both types occur with equal frequency, there will be in the fourth generation less than one person in ten thousand of pure descent. When the proportion of the two original types is as nine to one, there will be among the more numerous part of the population only eighteen in one thousand in the fourth generation that will be of pure blood. Taking these data as a basis, it is obvious that intermixture, as soon as the social barriers have been removed, must be exceedingly rapid; and I think it safe to assume that one hundred years from now, in the bulk of our population, very few pure descendants of the present immigrants will be found.

Unfortunately, however, we do not know the influence of racial cohesion. Obviously this is one of the fundamental points that ought to be known in order to gain a clear insight into the effect of recent immigration. The data collected by our census and by other agencies do not contain this information, which is one of the most urgent desiderata for an understanding of the composition of the American population. I may therefore express the hope that this question may be included in the census to be organized next year, or may be otherwise provided for by an inquiry to be undertaken under the auspices of the government. Without this information, the whole discussion of the effect of intermixture will remain speculative.

No material whatever is available to answer the question whether mixture of types is favorable for the physical development of the individual, or unfavorable. Statistics collected in the Argentine Republic tend to show that with a mixture of similar types, but from remote countries, considerable changes in the proportions of the sexes develop. Observations on half-breed Indians show that a type taller than either parental race develops in the mixed blood; that the fertility of the mixed blood is increased; and I can not find any evidence that would corroborate the view, so often expressed, that the hybrid of distinct types tends to degenerate.

I have refrained entirely from a discussion of the social problem, which is no less important than the one referring to the physical types of the descendants of immigrants; and I do not intend to include this question in our consideration, which is devoted to the anthropological problem only.

I have also devoted attention essentially to the biological problems presented by the immigration of European nations, but I must not conclude my remarks without referring at least to the serious problem presented by the negro population of our country. When compared with the contrast between the negro and the white, the differences of the European types seem insignificant; and the unity of the European race, as contrasted with the negro race, becomes at once apparent.

I do not intend to take up the whole question of racial inferiority, which can not be treated adequately in the brief time that I can devote to this subject. I must confine myself to a statement of my opinion, which I have repeatedly tried to substantiate. I do not believe that the negro is, in his physical and mental make-up, the same as the European. The anatomical differences are so great that corresponding mental differences are plausible. There may exist

differences in character and in the direction of specific aptitudes. There is, however, no proof whatever that these differences signify any appreciable degree of inferiority of the negro, notwithstanding the slightly inferior size, and perhaps lesser complexity of structure, of his brain; for these racial differences are much less than the range of variation found in either race considered by itself. This view is supported by the remarkable development of industry, political organization, and philosophic opinion, as well as by the frequent occurrence of men of great will-power and wisdom among the negroes in Africa.

I think we have reason to be ashamed to confess that the scientific study of these questions has never received the support either of our government or of any of our great scientific institutions; and it is hard to understand why we are so indifferent towards a question which is of paramount importance to the welfare of our nation. The anatomy of the American negro is not well known; and, notwithstanding the oft-repeated assertions regarding the hereditary inferiority of the mulatto, we know hardly anything on this subject. If his vitality is lower than that of the full-blooded negro, this may be as much due to social causes as to hereditary causes. Owing to the very large number of mulattoes in our country, it would not be a difficult matter to investigate the biological aspects of this question thoroughly; and the importance of the problem demands that this should be done. Looking into a distant future, it seems reasonably certain that with the increasing mobility of the negro, the number of full-bloods will rapidly decrease; and since there is no introduction of new negro blood, there can not be the slightest doubt that the ultimate effect of the contact between the two races must necessarily be a continued increase of the amount of white blood in the

negro community. This process will go on most rapidly inside of the colored community, owing to intermarriages between mulattoes and full-blooded negroes. Whether or not the addition of white blood to the colored population is sufficiently large to counterbalance this leveling effect, which will make the mixed bloods with a slight strain of negro blood darker, is difficult to tell; but it is quite obvious, that, although our laws may retard the influx of white blood considerably, they can not hinder the gradual progress of intermixture. If the powerful caste system of India has not been able to prevent intermixture, our laws, which recognize a greater amount of individual liberty, will certainly not be able to do so; and that there is no racial sexual antipathy is made sufficiently clear by the size of our mulatto population. A candid consideration of the manner in which intermixture takes place shows very clearly that the probability of the infusion of white blood into the colored population is considerable. While the large body of the white population will always, at least for a very long time to come, be entirely remote from any possibility of intermixture with negroes, I think that we may predict with a fair degree of certainty a condition in which the contrast between colored people and whites will be less marked than it is at the present time. Notwithstanding all the obstacles that may be laid in the way of intermixture, the conditions are such that the persistence of the pure negro type is practically impossible. Not even an excessively high mortality and lack of fertility among the mixed type, as compared with the pure types, could prevent this result. Since it is impossible to change these conditions, they should be faced squarely, and we ought to demand a careful and critical investigation of the whole problem.

It appears from this consideration, that

the most important practical questions relating to the negro problem have reference to the mulattoes and other mixed bloods—to their physical types, their mental and moral qualities, and their vitality. When the bulky literature of this subject is carefully sifted, little remains that will endure serious criticism; and I do not believe that I claim too much when I say that the whole work on this subject remains to be done. The development of modern methods of research makes it certain that by careful inquiry, definite answers to our problems may be found. Is it not, then, our plain duty to inform ourselves that, so far as that can be done, deliberate consideration of observations may take the place of heated discussion of beliefs in matters that concern not only ourselves, but also the welfare of millions of negroes?

Facts that could help us to shape our policies in regard to our race problems are almost entirely wanting. It has been my endeavor to show that by proper investigations much can be done to clear up these problems, which are of vital importance for the future of our nation.

FRANZ BOAS

COLUMBIA UNIVERSITY

THE INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY

We take from the *London Times* some facts in regard to the seventh International Congress of Applied Chemistry, which will be opened at the Albert Hall, London, on May 27.

Previous congresses have been held in Brussels in 1894, in Paris in 1896 and 1900, in Vienna in 1898, in Berlin in 1908 and in Rome in 1906; this is therefore the first occasion on which Great Britain has been visited. The work of the congress has grown steadily, and its importance is realized all over the world. There is ample evidence of the interest taken in Great Britain, where in addition to Royal patronage the congress has received the support of several of the heads of

the government departments who have become honorary vice-presidents. Sir Henry Roscoe, F.R.S. and Sir William Ramsay, F.R.S., are honorary president and acting president, respectively.

For some considerable time an organizing committee has been making the arrangements for the congress and has had the support, as vice-presidents, of the presidents of the Royal Society, the Society of Chemical Industry, the Institute of Chemistry, the Institute of Brewing, the Society of Dyers and Colorists, the Pharmaceutical Society, and the Society of Public Analysts, Sir William Abney, F.R.S., Sir Hugh Bell, Professor P. F. Frankland, Dr. J. Lewkowitsch, Dr. L. Mond, F.R.S., Dr. E. K. Muspratt, Sir Boverton Redwood, Mr. W. E. Reid, Mr. A. Gordon Salamon and Professor W. A. Tilden, F.R.S. The committee is a large one and includes in addition to representatives of the organizations already named members of the Royal Societies of Edinburgh and Dublin, the Royal Society of Arts, the Iron and Steel Institute, the Institution of Mining Engineers, the Institution of Mining and Metallurgy, the International Association of Leather Chemists, the Royal Agricultural Society of England, the Lawes Agricultural Trust, the Royal Photographic Society, the Faraday Society and the London Chamber of Commerce (Chemical Trade Section), with Mr. William MacNab as honorary secretary. In connection with this committee local committees are formed in the principal centers of the British Isles and foreign countries and the colonies with a view to furthering the interests of the congress.

The work of the congress covers a wide field, as is shown by the large number of sections into which it is divided, as follows: (1) Analytical Chemistry (president, Dr. T. E. Thorpe, O.B., F.R.S.); (2) Inorganic Chemistry and Allied Industries (Dr. Ludwig Mond, F.R.S.); (3) Metallurgy and Mining. Explosives—(a) Metallurgy and Mining (Sir Hugh Bell), (b) Explosives (Sir Andrew Noble, F.R.S.); (4) Organic Chemistry and Allied Industries—(a) Organic Products (Professor W. H. Perkin, F.R.S.), (b) Coloring Substances and their Uses (Professor Meldola, F.R.S.); (5)

Industry and Chemistry of Sugar (Mr. Richard Garton); (6) Starch Industry—(a) Starch Industry (Dr. Horace T. Brown, F.R.S.), (b) Fermentation (Mr. John Gretton, M.P.); (7) Agricultural Chemistry (Lord Blyth); (8) Hygiene, Medical and Pharmaceutical Chemistry. Bromatology—(a) Hygiene and Medical Chemistry (Sir J. Orichton Browne, F.R.S.), (b) Pharmaceutical Chemistry (Mr. N. H. Martin), (c) Bromatology (Mr. Robert R. Tatlock, F.I.O.); (9) Photographic Chemistry (Sir William Abney, F.R.S.); (10) Electrical and Physical Chemistry (Sir John Brunner, M.P.); (11) Law, Political Economics and Legislation with reference to Chemical Industries (Lord Alverstone).

The sections will meet in the buildings of the University of London and the Imperial College of Science and Technology each day of the congress from 10 o'clock to 1:30 (except on the closing day), and on May 31 and June 1, from 4 to 6. On the evening of Wednesday, May 26, the day before the official opening, the mayor and the corporation will hold a reception of the delegates at the Guildhall. The prince of Wales will open the congress at the inaugural meeting to be held at the Royal Albert Hall on May 27, at 3 o'clock, and in the evening of that day a reception will be held by the foreign office. At 2:30 on Friday, May 28, lectures will be delivered to the whole congress by Professor Haller, of Paris, and Professor Paterno, of Rome, and at Crystal Palace in the evening a banquet will be held, at which it is expected a large number will be present. A garden party will be held at the Botanic Gardens on Saturday, May 29, by the ladies' committee, which has been formed, under the presidency of Lady Ramsey, for the purpose of entertaining the ladies accompanying the members; and later in the day a reception will be held by the London section of the Society of Chemical Industry at the University of London. On Monday, May 31, Professor Otto de Witt, of Berlin, will give a general lecture at 2:30, and at the same hour on the following day, June 1, Sir Boverton Redwood is announced to deliver a lecture to the whole congress. In the

evening of Tuesday, June 1, a reception will be held at the Natural History Museum. The official closing of the congress will take place at a meeting held at 10 o'clock on June 2. In the afternoon members will, by permission of the King, visit Windsor Castle.

The offices of the honorary general secretary, Mr. William MacNab, are at the Imperial College of Science and Technology, South Kensington.

THE SUMMER MEETING OF THE AMERICAN CHEMICAL SOCIETY

THE summer meeting of the American Chemical Society will, as already announced, be held in Detroit, Mich., on June 29 to July 2, inclusive. On the previous day a business meeting of the council will be held. The meetings of the sections and divisions will be held on Tuesday and Wednesday, June 29 and 30, and on Friday, July 2, in the Central High School, which has ample facilities.

On Tuesday evening a complimentary smoker will be given by the Society of Detroit Chemists to the members of the American Chemical Society.

On Wednesday afternoon the members will inspect the works of Parke, Davis & Co., to be followed by a lunch and a moonlight boat-ride on the Detroit River, complimentary to the visiting chemists from this firm.

On Thursday the members will take special cars to the University of Michigan at Ann Arbor, where they will be the guests of the University of Michigan for the day, returning to Detroit in the evening for the usual banquet. The program will be continued on Thursday at the University of Michigan and will consist mainly of special papers of wide general interest.

On Friday the sectional and divisional programs will be continued and excursions taken to manufacturing plants in Detroit.

The headquarters for the meeting will be at the Hotel Pontchartrain. Details in regard to this hotel and other hotels in Detroit may be obtained by addressing the secretary. It is suggested by the local committee that it is very necessary to make hotel reservations in

advance, as Detroit is liable to be crowded at this time.

Special arrangement is being made for the entertainment of ladies who accompany members.

CHARLES L. PARSONS,
Secretary

DURHAM, N. H.

FORMATION OF THE JOINT COMMITTEE ON THE UNIFICATION OF METHODS OF ANALYSIS OF FATS AND OILS

At the last meeting of the Association of Official Agricultural Chemists, held in November, 1908, a committee of three was appointed to join with a similar committee, if such could be appointed, from the American Chemical Society and the American Society for Testing Materials, the object being to try to bring about uniformity in the methods of these three great chemical societies, and also that this joint committee should represent this country in the formation of an international commission upon this same subject.

The committee appointed by the Association of Official Agricultural Chemists consisted of Mr. L. M. Tolman, chairman, Mr. Percy H. Walker and Mr. A. Lowenstein. The committee from the American Chemical Society consisted of Mr. A. H. Gill, chairman, Mr. David Wesson and Mr. C. E. Waters. The committee appointed by the American Society for Testing Materials consisted of Mr. C. N. Forrest, chairman, Mr. Jerome Frank and Mr. G. W. Thompson. These three committees have united into the formation of a joint committee, Mr. Tolman being elected chairman, and Mr. Forrest, secretary.

The work of this joint committee is to bring about as far as possible a uniformity in methods of analysis and statement of results. The first meeting was held in New York at the Chemists' Club on May 25, for the consideration of plans of work, and of carrying them on.

THE PUGET SOUND MARINE STATION

A LABORATORY for the study of marine biology has been established by the State University, the State College and the three State

Normal Schools of Washington in cooperation. This is located on the islands of the lower Puget Sound, a region unapproachable for its wealth of marine life. For the session 1909 the laboratory will be maintained at Friday Harbor on San Juan Island from June 21 until July 10, and at Olga on Orcas Island from July 12 until July 31. The following courses are announced: Exploratory Zoology, C. T. Brues, curator of the Milwaukee Public Museum; Invertebrate Zoology, H. S. Brode, professor of biology, Whitman College; Vertebrate Zoology, A. D. Howard, professor of zoology, University of Washington; Insects, A. L. Melander, professor of entomology, Washington State College; Molluscs, James L. Kellogg, professor of zoology, Williams College; Fishes, E. C. Starks, curator, Stanford University; Phylogeny of Plants, Charles E. Bessey, professor of botany, University of Nebraska; Cryptogamic Botany, Charles O. Chambers, professor of biology, Pacific University; Systematic Botany, R. K. Beattie, professor of botany, Washington State College; Ecology, T. C. Frye, professor of botany, University of Washington; Algae, Mabel R. Simpson, professor of biology, University of Puget Sound.

The equipment of the station will include a steam dredging outfit, motor launch, scows, boats, etc. Microscopes and usual apparatus will be supplied. Tuition is free, but a laboratory privilege charge of ten dollars will be made for the six weeks courses. The Alaska-Yukon-Pacific Exposition at Seattle will afford an unusual opportunity of visiting the Pacific coast at low cost.

An invitation to make the station their headquarters is cordially extended to eastern biologists. Every opportunity will be given for the collection and study of the interesting species of Puget Sound. Correspondence may be addressed to Professor T. C. Frye, University, Seattle, or to Professor A. L. Melander, Pullman, Washington.

THE BIOLOGICAL STATION OF THE UNIVERSITY OF MICHIGAN

A STATION for instruction and research in biology will be maintained by the University

of Michigan, as a part of its regular summer session, during the eight weeks from June 28 to August 20 inclusive, 1909.

The station will be located near the Bogardus Engineering Camp of the university on a tract of about 1,700 acres of land owned by the university and stretching from Douglas Lake to Burt Lake in Cheboygan County, Michigan, seventeen miles south of the Straits of Mackinaw. This region, diversified by hills and valleys, was formerly covered by primeval forest, and vestiges of this still remain. It contains many lakes of clear water, unsurpassed in the state for size, depth and beauty of setting. The elevation of the camp, between two and three hundred feet above Lake Michigan, insures cool nights and makes the location favorable for hay fever sufferers. The topography of the region immediately about the Bogardus Camp is such as to afford a variety of floral and faunal conditions.

It is not the purpose of the station to duplicate the work offered at the university, but to provide facilities for field work of a sort that can not be so well carried on at the university or under the limitations imposed by a university schedule.

The courses of instruction will include: The natural history of vertebrate animals, freshwater special work and research in zoology, teachers' course in ecology, identification of trees and shrubs, botanical survey of the Bogardus Camp region, and research in ecology. Professor Reighard, head of the department of zoology, and Dr. George P. Burns, assistant professor of botany in the University of Michigan, will be in charge of these courses.

Not more than twenty students can be accommodated, and no registration will be accepted if received after June 10. Applications should be addressed to Professor E. H. Kraus, secretary of the Summer Session, Ann Arbor, Mich.

SCIENTIFIC NOTES AND NEWS

MR. OAKES AMES has been appointed director of the Botanic Garden of Harvard University.

DR. R. R. GATES, of the University of Chicago, has accepted a position in the Missouri Botanical Garden, where he will devote himself to continuing his cytological experiments and breeding experiments with *Utricularia*.

DR. R. P. VERNEAU has been appointed to the professorship of anthropology in the Paris Museum of Natural History in succession to the late Professor Hamy.

DR. CHALMERS MITCHELL, secretary of the London Zoological Society, will reside at the gardens when the society's library and offices are transferred there. Under him there will eventually be three curators, one each for mammals, birds and reptiles. Mr. R. I. Pocock, who is to retain his present post of garden-superintendent, will have charge of the mammals, and temporarily of the reptiles, while Mr. D. Seth-Smith is to take over the custody of the birds, combining with this duty the office of inspector of works.

DR. FREDERIC WARD PUTNAM, Peabody professor of American archeology and ethnology in Harvard University, has resigned from active service. It will be remembered that Professor Putnam celebrated his seventieth birthday on April 16.

PROFESSOR VIKTOR VON LANG has retired from the chair of experimental physics at Vienna.

A PORTRAIT of Dr. James Law, the first director of the Veterinary College of Cornell University, has been presented to the college as a gift of the New York state alumni. The presentation was made by Dr. G. S. Hopkins, and the portrait was accepted on behalf of the university by President Schurman. Addresses were delivered by ex-President White and Director Moore.

THE faculty of the Massachusetts Institute of Technology at the last regular faculty meeting of the year adopted the following resolution by a unanimous rising vote:

Resolved, That the members of the faculty of the Massachusetts Institute of Technology desire to express to Dr. Arthur A. Noyes, upon his concluding his work as acting president, their deep

sense of the service he has rendered by his admirable executive ability, his power of initiative, his untiring labor, his unfailing tact and his contagious enthusiasm. Under his skilful management a period which might easily have been one of discouragement and detriment has been marked by distinct and constant advance in the affairs of the school, and by the inception and progress of new and excellent measures in its administration. They also wish to declare their admiration for the unselfishness with which he has laid aside for the time being the original work in which he has gained such distinction, in order to devote his energy to the interests of the institute as a whole; and they thank him for the kindly and helpful spirit which has marked all his relations toward them, both official and personal.

The students have presented Dr. Noyes with a loving cup bearing an inscription as follows:

Presented to Dr. Arthur A. Noyes by the undergraduates of the Massachusetts Institute of Technology in gratitude for his faithful and efficient service, his warm-hearted sympathy and his unselfish devotion as acting president, 1907-1909.

We are glad to learn that Dr. Edgar F. Smith, head of the department of chemistry and vice-provost of the University of Pennsylvania, has resumed academic duties after a long illness.

PROFESSOR JULIUS WIESNER has been elected a corresponding member of the Paris Academy of Sciences in the section of botany.

THE Royal Scottish Geographical Society has decided to award its Livingstone gold medal for the current year to Lieutenant Shackleton for his exploration in the Antarctic.

LIVERPOOL UNIVERSITY has conferred its doctorate of science on Mr. Francis Darwin and Professor J. L. Todd; its doctorate of engineering on the Hon. C. A. Parsons, and its doctorate of laws on Sir Donald Macalister and Mr. William Marconi.

DR. CHARLES W. ELIOT will give the commencement address at the University of Missouri on June 2, at the same time the doctorate of laws will be conferred on him.

MCGILL UNIVERSITY, of Montreal, intends to confer the honorary degree of LL.D. on Dr. George A. Gibson, of Edinburgh, at the medical convocations on June 9. Dr. Gibson gave the inaugural address before the medical faculty of the university on September 22, 1908, his subject being "The Limits of Knowledge."

FOR the superintendence of the investigations at the National Physical Laboratory and for general advice on the scientific problems arising in connection with the work of the British Admiralty and War Office in aerial construction and navigation, a special committee has been appointed, which includes the following: President, the Right Hon. Lord Rayleigh, O.M., F.R.S.; chairman, Dr. H. T. Glazebrook, F.R.S. (director, National Physical Laboratory); Major-General Sir Charles Hadden, K.C.B. (representing the army), Captain R. H. S. Bacon, R.N., C.V.O., D.S.O. (representing the navy), Sir Alfred G. Greenhill, F.R.S., Dr. W. N. Shaw, F.R.S. (director, the Meteorological Office), Mr. Horace Darwin, F.R.S., Mr. H. R. A. Mallock, F.R.S., Professor J. E. Petavel, F.R.S., and Mr. F. W. Lanchester.

DR. L. O. HOWARD, chief of the bureau of entomology and permanent secretary of the American Association for the Advancement of Science, is in Europe to continue his study of parasites with which the ravages of the gypsy moth may be checked.

PROFESSOR N. E. GILBERT, of Dartmouth College, will spend a large part of the next year in study and investigation at the Cavendish Laboratory, Cambridge, England.

THE Senckenberg Natural History Society has awarded the Sömmerring prize to Dr. Paul Krämer, of Vienna, for his work on the inheritance of artificially produced reproductive adaptations.

PROFESSOR R. M. YERKES, of Harvard University, addressed the Scientific Association of the Johns Hopkins University on May 12 upon the "Scientific Method in the Study of Comparative Psychology," showing the importance of applying quantitative methods in the investigation of its phenomena.

PROFESSOR TAAV. LAITINEN, M.D., professor of hygiene and director of the Hygienic Institute in the University of Helsingfors, and chairman of the Finnish National League of Health, will deliver the third Norman Kerr Memorial lecture on July 20, in the lecture theater of the Victoria and Albert Museum, London. The subject will be "The Influence of Alcohol on Immunity."

THE Harben lectures of the Royal Institute of Public Health, London, will be delivered this year by Professor R. Pfeiffer, director of the Hygienic Institute, Breslau, in the lecture room of the institute.

THE directorship of the Pathological Institute of the New York State Commission in Lunacy is to be filled by civil service examination. Candidates must meet the following requirements: Five years' residence in a large public or private hospital for the insane; five years' experience as a successful instructor in neuropathology or psychiatry, or as chief of clinic; familiarity with German, French and English; familiarity with the insanity law of New York State and the administration of the department under the Commission in Lunacy; evidence of original research shown by contributions to clinical psychiatry, pathological anatomy of the nervous system, experimental psychology, etc. All submitted papers must be properly authenticated and reach the State Civil Service Commission on or before June 19. Candidates should give in their applications detailed information concerning their training and experience, especially in the lines mentioned. Subjects of examination and relative weights: psychiatry and psychopathology, 3; neurology and neuropathology, 3; experience and special training, 4. The salary of the position is \$6,500.

THE councilors of the American Geographical Society have accepted Mrs. Collis P. Huntington's gift of a \$250,000 site for a new building at Broadway and 153d Street, New York City, overlooking the Hudson River. Mr. Archer M. Huntington, the president of the society, has given \$50,000 toward the building fund, which will be increased by further subscriptions and the proceeds of the

sale of the old building, which should be about \$250,000.

THE two-ton iron meteorite found in 1908 near Tonopah, Nevada, has recently been presented to the Field Museum of Natural History through the generosity of Messrs. Stanley Field, Richard T. Crane, Jr., Cyrus H. McCormick and George F. Porter.

THE London *Times* states that Dr. Rendle, keeper of the botanical department of the British Museum (Natural History) at South Kensington, has just completed the rearrangement of the botanical gallery of that museum. The main series of exhibits represents the great plant groups with their families, including flowering plants, ferns, mosses, seaweeds and fungi. The groups are illustrated by pictures, specimens and models. The series of exhibits illustrating the British flora is rapidly approaching completion. The drawings of the larger British fungi are complete. The trustees, it may be mentioned, have just issued a handbook giving descriptions of all known British species illustrated by line drawings of the genera. There is a very interesting series of actual specimens of the larger fungi found near London, mostly on Wimbledon-common. These have been prepared in such a way as to show the structure. The British flowering plants, ferns and mosses are displayed in frames in such a way as to be easy of reference. This collection is intended not so much for the expert botanist as for the amateur who may wish to identify specimens without being under the necessity of a prolonged search in the great herbarium of the museum. Some volumes of illustrations of British plants are also available for consultation by the public. They are a recent acquisition, having been given by the artist, Miss E. N. Gwatkin. The lichens of Britain have been arranged in two cabinets, with descriptions and original drawings. The collection also contains cases illustrating points in the biology of plants, the fertilization of flowers, insect-eating flowers, parasitic plants, plants from dry countries, climbing plants and others. A case showing the abnormalities of leaves, flowers and fruits has also been arranged.

It has been estimated that the amount of wood annually consumed in the United States at the present time is twenty-three billion cubic feet, while the growth of the forest is only seven billion feet. In other words, Americans all over the country are using more than three times as much wood as the forests are producing. The figures are based upon a large number of state and local reports collected by the government and upon actual measurements. The state forester of Connecticut, in a recent report, has given figures on growth and use for New Haven County, which give more details than are generally to be obtained, and illustrate how the forest is being reduced by over-cutting. In this county a very careful study was made on each township of the amount of forest, the rate of growth, and the amount of timber used. For the year 1907 the timber used was 120,000 cords, in the form of cordwood, lumber, ties, poles and piles. The annual growth on all types of forest land, including the trees standing on abandoned fields, for the year, reached a total of 70,000 cords. Thus the amount cut yearly exceeds the growth by 50,000 cords. The amount of standing timber considered as merchantable and available for cutting within the next few years was found to be 1,200,000 cords. Each year the annual growth increases the supply on hand by 70,000 cords, while the use decreases it by 120,000. The net reduction is therefore 50,000 cords a year. If the cut and the growth remain at the present figures, the supply of merchantable timber will be exhausted in about twenty years. At the end of that time there will be a large amount of forest standing in the county, but it will be in tracts under forty years of age, containing wood below the most profitable size for cutting. Cordwood could still be cut, but supplies of the most profitable products, like ties and lumber, would be practically exhausted.

UNIVERSITY AND EDUCATIONAL NEWS

Mrs. MORRIS K. JESUP has given Yale University \$100,000 to establish the Morris K. Jesup chair of agriculture in the For-

estry School. The university has also received \$50,000 for the School of Fine Arts and \$50,000 for a memorial gateway.

Dr. W. G. FROST, president of Berea College, announces that an industrial school for negroes will be established near Shelbyville, Ky., and the erection of buildings will be begun in a short time. A railroad station and a post office for the school will be established, called Lincoln, Ky. The endowment, largely given by Mr. Andrew Carnegie, amounts to \$350,000.

THE University of Pennsylvania has asked the city of Philadelphia to transfer to it sixty-one acres of land adjoining the grounds of the institution in return for fifty free scholarships. The land wanted extends east to the Schuylkill River.

THE Goldsmith Company has given £50,000 to the Imperial College of Science and Technology, London, for a building extending the engineering department.

THE Bristol Town Council has decided to contribute in the proportion of one penny in the pound on the rate, or about £7,000 per annum, towards the support of the proposed university for Bristol and the west of England, for which more than £200,000 has been subscribed, mainly by members of the Wills family.

Dr. EDWARD L. EARP has resigned his position as professor of sociology at Syracuse University to accept the chair of Christian sociology at Drew Theological Seminary, Madison, N. J.

MR. T. H. LABY has been appointed to the chair of physics in Victoria College, Wellington, New Zealand.

Dr. M. CUTTA, associate professor in the Technological School at Munich, has been called to a chair of applied mathematics in the University of Jena.

DISCUSSION AND CORRESPONDENCE

SOME NEW DATA ON THE PROFESSOR'S FINANCIAL POSITION

A TEACHER on entering the profession generally tacitly assumes that after a certain

length of time of greater or lesser duration, and upon evidence of ability and progress along required lines, that promotion and salary will come of themselves.

That the expectation is small and that the realization is still smaller is a fact which soon impresses itself upon all in the teaching profession.

From personal observation, I believe that many are enticed into the career of teaching without due regard as to the discouraging pecuniary future, and I wish to suggest that all those desiring to teach be carefully made to see what the future has in store for them.

A teacher's salary is notably smaller than that which men of the same or even lesser ability obtain in other occupations; but I believe that teachers, as a class, have considered this but of small consequence and are not, as a class, envious of the far greater incomes of most of those with whom they meet in a social way.

They come under the class of salaried men who take no risks and hence do not share in the excess profits. A distinguished sociologist on my enquiry as to the position of the professor in the sociological order answered "You are all parasites." To a great measure this is correct, we are parasites, happily useful ones, but still parasites.

We are resigned to our fate; but lately some facts have come to my notice that have aroused my sense of justice and made me view with much less equanimity the low financial position of the teacher.

I have before me an authoritative manuscript by Colonel H. O. S. Heistand, of the Adjutant General's Department, U. S. Army, entitled "The United States Army as a Career."

The following extract is the portion which excites these feelings and also others which I believe most of those that read will have in common with me:

THE ARMY AS A CAREER

Let us see what the enlisted man is able to do in the way of accumulating a competence to provide for the declining years of his life.

If he has been an improvident spendthrift

throughout his entire career and has not saved a penny, he will have as long as he lives his retired pay, which at the very least is equal in value to a paid-up insurance policy of from \$10,000 to \$20,000, non-forfeitable and guaranteed by the government. But a careful man would save half his cash pay when all necessities are provided, and let us see what would be the result if he did so.

If he has remained a private soldier—the very lowest position in the army—during his entire twenty-five or thirty years' service, without ever having received any "extra-duty" pay or other special increase, and has saved and deposited with the government one half of his pay, and the amounts due him on discharge each time he reenlists, he finally quits the active list with the snug sum of more than \$9,000, the income of which at four per cent. would yield over \$30 per month; this added to his retired pay gives him a monthly income of nearly \$65 per month for the rest of his life, and he is free to go wherever and occupy himself as he pleases.

Please notice that in this case and in the following cases the men own their capital and may withdraw it to go into business; and also that they are still comparatively young, that is, between 43 and 50 years of age, assuming that they enlisted between the ages of 18 and 25 years.

But for a soldier to remain a private so long is almost impossible; such a condition could result only from excessive indolence or a degree of stupidity that would seem to be a bar to original or subsequent enlistment. A fair supposition and one easy of realization would be that of a soldier who remains a private half of his first enlistment, then becomes a corporal; is made a sergeant upon reenlistment, and remains a sergeant the remainder of his career. Such a soldier, saving as above, would receive on final discharge nearly \$15,000, this amount at four per cent. together with his retired pay would give him a monthly income of over \$100 for the remainder of his life.

If instead of remaining a sergeant he reaches the grade of first sergeant and holds that position during the last nine years of his service, he will have saved about \$16,000, which at four per cent. will yield an amount, which added to his retired pay, gives him over \$120 per month. If the soldier is a private during his first enlistment, a sergeant in his second and third enlistments and then becomes a non-commissioned staff officer, say a commissary sergeant, his savings of one half

his pay, etc., as above, will amount to over \$18,000 and with his retired pay will provide him an income of about \$130 per month.

But even this by no means exhausts the possibilities of a career in the ranks of the army. For, if, say during the first three enlistments the soldier diligently applies himself to study in the army schools which are provided for him and advances sufficiently to become a master electrician, or if he have a musical turn and become a chief musician or sergeant in the band, his savings at the date of retirement will be just short of \$24,000 and his total monthly income will be almost exactly \$170.

None of the above cases are exceptions—all are within easy realization of the enlisted man who enters the army for a life business with a determination to succeed and prosper. Furthermore, at the date of retirement he will be in the prime of life and able to add to his capital and income for many years. Observation leads to the belief that very few laboring men or mechanics achieve a measure of success equal even to that possible for the soldier who remains a private during his entire career, and the easy possibility of the higher grades exceeds the average of success of the learned professions.

Men in business and professional life may contemplate a greater measure of success than this, but in doing so the great majority of them indulge only in pleasant dreams which are never realized. They suffer the dangers of fire, bank failures, industrial depressions and all the other enemies of success against which the professional soldier has the integrity and permanency of the government to protect him.

If the soldier does not desire to remain in the army for the full period of thirty years, he may quit at the expiration of any enlistment period, or he may purchase his discharge at any time after one year's service if he be not undergoing punishment or is not on duty at or under orders for duty at a foreign station; and if he chooses to save his money he will have between \$300 and \$400 at the end of a single enlistment. Surely he will not have wasted his time. After twenty years' service he may enter the Soldier's Home which is maintained by the federal government in the District of Columbia, and there spend his days in comfort.

Inquiry elicited the facts, which were to be expected, that a very similar outlook encouraged the *enlisted* man in the navy.

It seems to us that these extracts speak for

themselves. The only requirements of admission of a man to all of these possibilities is simply that he be of sound body, of good moral character and be able to read and write English (1).

In comparison with what is required of the college professor the teaching profession has not a tenth of similar advantages to offer.

We can not retire without losing all claim to a pension, if we do so before a certain large number of years of service have passed.

The average teacher retires an old man after his energies have been used up in the furtherance of the public good that repays him so meagerly.

The pension, when it is obtained, is not nearly so large, in most cases, as that received by the soldier who, besides, *owns* a goodly part of the contributing capital.

All this is about the *enlisted* man. The officers have, of course, a more remunerative future before them.

The young cadet on graduation receives a minimum salary of \$1,700 as second lieutenant. If he becomes first lieutenant or captain, which may occur very shortly, or at least the salaries of which grades he may receive shortly, his salary rises to \$2,000 and \$2,400 respectively. The salary of a major is \$3,000. All salaries are subject to a ten per cent. increase every five years for twenty years if promotion should by any accident not take place long before that period is ended.

Besides these amounts the officers are allowed quarters and light for themselves and families and the privilege of obtaining all supplies at wholesale rates through the commissary department.

When in course of duty the officer must reside outside of the army post, the government allows him an extra amount called commutation of quarters, of respectively \$24 per month for second lieutenants, \$36 per month for first lieutenants, \$48 to captains, the amounts increasing by \$12 a month for each grade.

Adding this to the nominal salary and a percentage saving of one fifth or twenty per cent. in the cost of provisions, we have the totals for a newly graduated cadet or second

lieutenant, about \$2,800, for a first lieutenant about \$2,800, for a captain about \$3,400. These are all low grades in the army.

What teacher receives anything approaching this on graduation from a college or even on receiving a doctor's degree after six more arduous years of hard study?

The salary on graduation of a Massachusetts Institute of Technology man as assistant is \$500, with an increase to \$600 the next year. It may in some institutions reach as high as \$1,000, but that is exceptional.

A common soldier may reasonably look forward to retirement at the age of 45 or 50 years, with a life-long income of \$2,040, and the opportunities to devote himself to a congenial pursuit.

One feels a certain amount of chagrin in meeting casually on a train an enlisted naval petty officer younger than himself who has \$12,000 saved in the bank.

Why must the teaching profession be forever in such an unfortunate financial position in comparison with other callings? Have we not, as a class, enough common interest, enough moral courage to wage a campaign together for what is justly due us, for our labors? That is, a reasonable salary sufficient for our needs, sufficient for our family, sufficient to maintain the responsible and honorable position we now hold and which would in the event of a just increase become of much more influence in public life.

J. G. COFFIN

FAIR PLAY AND TOLERATION IN SCIENCE

TO THE EDITOR OF SCIENCE: I have read with surprise, if not indignation, Professor Blackwelder's discussion of Lowell's "Mars as the Abode of Life" in your issue of April 23, 1909; and feel that it is only just to enter a protest, in the interest of fair play and that degree of toleration which has always been characteristic of the better men of science. Professor Blackwelder speaks as if some great injury had been done to the public by the appearance of a popular book, written in a narrative style adapted to the lay demand. Of course this is wholly untrue, and mere idle

vaporings. Lowell's popular works are all better than Proctor's and Flammarion's, and both of these latter writers have done valuable service in diffusing the results of scientific research among the multitude. It may sound very plausible to the scientific recluse to say that nothing but mathematical formulae and tables are of value, but every well-informed man knows better. It is by the popularization of science that new interest is awakened in the public mind and increased opportunities provided for the extension of scientific research.

To take a specific example, it was the reading of a popular work by Huyghens, entitled "Comotheoros," which led Dr. Plume to establish the Plumian professorship of astronomy at Cambridge, which has been held by such distinguished mathematicians as Sir George Darwin, who has greatly extended our knowledge of mathematical astronomy, yet is not so narrow as to deny the value of popular science, but on the contrary has contributed to it by popular articles in magazines and a standard work on the tides.

If we compare the present state of astronomy in the United States with that in other countries, we shall be compelled to admit that American preeminence is due very largely to popular interest, and a general appreciation of results. Without popular diffusion of the results of scientific research, who among our business men and captains of industry could possibly have any interest in scientific work? In this day of specialization even scientific workers find it difficult to understand the labors of others, and the public is at vastly greater disadvantage. I make great use of logarithms, trigonometry and calculus, but I have yet to see the laymen who enthuse over columns of figures or complicated mathematical analysis.

When Proctor was living he was assailed by the self-appointed critics in much the same way as Lowell is now; but they always forget that there are others to be considered besides the mere priesthood of science. It sometimes seems to me that some of the latter are almost as intolerant as those divinely inspired persons who took it upon themselves to conduct

the inquisition during the middle ages. For one, I am not at all prepared to admit the justice of contemporary criticism, though in the long run a moderate and just opinion will prevail. This has been true in all ages and professions, and therefore is not confined to our own time or to any particular science.

Now as to some of the points cited by Professor Blackwelder as objectionable:

1. He finds fault with Lowell for adhering to Laplace's cosmogony; but let me point out that this same cosmogony very slightly modified, to take account of tidal friction, has been held by the most eminent mathematicians abroad.¹ If such views have been held by those who have spent many years on the subject, at such mathematical centers as Cambridge, England, surely Lowell may be excused for not accepting the inconsistent and purely destructive criticisms recently put forth at Chicago by Chamberlin and Moulton. It is only fair to say that no constructive results of consistent character had been reached on this subject till my own investigation was completed last year, of which an account is given in *Astronomische Nachrichten*, No. 4308 (February, 1909), but which appeared too late to be used in Lowell's book. As I have worked on this subject uninterruptedly for twenty-five years, I am prepared to speak with some degree of authority. If Professor Blackwelder will study my last paper carefully, and the work now in press, when it appears, he will find that most of the recent speculations on cosmogony are not worth the paper they are written on; and yet some of them have been published by the *Astrophysical Journal* and the Carnegie Institution, just as other erroneous and misleading papers have often been published by the Royal Society, the Paris Academy of Sciences and other learned societies of standing. Every experienced investigator recognizes the great amount of error that creeps into scientific literature even of the best type. How much more latitude, therefore, is to be expected in popular literature,

which in the nature of the case must be entertaining rather than strictly exact and ultra-conservative!

2. Great fault is found with Lowell's claim that in general the terrestrial continents have been formed from the interior outwards, though he justly cites Dana, one of the greatest geologists of any age, in support of this view. Now I venture to say that Professor Blackwelder has not read carefully the four memoirs recently published in the *Proceedings of the American Philosophical Society* at Philadelphia, in which I have examined this question and the related topics with great care; otherwise he would see that, however deficient our knowledge may be as to details, in general his contentions are absolutely without foundation. In the opinion of many eminent men of science, including some of the foremost geologists and physicists, who have done me the honor to read these papers, I have proved that mountains are formed by the sea, and not at all by the shrinkage of the globe; and as the younger mountains are generally nearest the oceans it follows that the oceans are gradually drying up and the land increasing, as Lowell maintains. Therefore Lowell is right, and Blackwelder wrong; and that too in a subject which he represents as his own. Dana and Le Conte clearly understood that the mountains are related to and have in some way risen from the sea, but on the old contraction theory, now happily abandoned, they could form no correct conception of the cause of mountain formation. If Professor Blackwelder is prepared to contest my results, let him answer my argument on mountain formation in the case of the Aleutian Islands, where I have proved that they are a submarine mountain range now being pushed up by matter expelled from beneath the trench dug out in the sea bottom to the south of these islands; and that the whole movement is due to the secular leakage of the ocean and the resulting expulsion of lava beneath the crust, and nothing else. On this point other geologists have discreetly kept silent, but perhaps Professor Blackwelder "will rush in where angels fear to tread."

¹Cf. paper by Mr. F. J. M. Stratton, on "Planetary Inversion," in the *Monthly Notices of the Royal Astronomical Society*, April, 1906.

3. Now in regard to life on Mars, it is sufficient to say that Professor Newcomb has justly remarked that the physical conditions on that planet are very similar to those prevailing in the Himalayas of Central Asia. But even the tableland of Tibet is inhabited, and maintains a respectable civilization. As Lowell has proved that there are water and clouds on Mars, and the polar snows melt and disappear with the advance of the summer seasons on that planet, why may there not be life there as well as here? Of course there is life on Mars; there is no doubt about it. But I am not prepared to say how far advanced the creatures on Mars may be; neither am I narrow enough to deny the possibility of their high development.

Perhaps it will interest Professor Blackwelder and others to know that I have just sent to the *Astronomische Nachrichten* and to the American Philosophical Society extracts from a letter of Euler, written in 1749, and published in the *Philosophical Transactions* of the Royal Society, before the cosmogonic theories of Kant (1755) and Laplace (1796) were put forward, in which the great Swiss mathematician, then residing at Berlin, even went so far as to say that the planets had gradually neared the sun from a great distance—thus implying that the earliest life originated on these bodies in the depths of space, before they came anything like so near the sun as they now are. Arrhenius holds a similar view to-day, and even thinks that life is carried by germs from one world to another.* In the work now in press, it is shown, on new grounds, that all the fixed stars are attended by systems of planets. Is Professor Blackwelder prepared to claim that all these billions of worlds are uninhabited? If not, why is he so unreasonable about the habitability of Mars? Lowell's view that there is life in the other worlds is sure to triumph, and we had as well come to it one time as another.

4. Professor Blackwelder is sure that Lowell is working for "a certain notoriety and a brief but undeserved credence for his pet theories." Let us, in common fairness, have

* Cf. "Worlds in the Making," *Harper's*, 1908.

no assignment of motives. These are seldom known in any man, either by himself or by others. If Professor Blackwelder is as candid as he wishes others to be, he will now come forward and say that there is much yet to be learned in every branch of science, including geology, and about contemporary scientific investigators as well, and that according to the best ethics, every tree must be judged by its fruit.

Lowell has maintained for fifteen years a magnificent observatory, which has carried on valuable work on Mars, and the other planets and satellites; on double stars, both visual and spectroscopic; on the spectra of the outer planets; on comets and meteoric phenomena; on meteorology as related to the best sites for observatories; and on many other topics. He has given many young astronomers a chance to do good independent work, and the results obtained are highly valued throughout the world. What has Professor Blackwelder done in comparison? And is he the one to say that censure can not be too severe upon one who has deserved so well of American men of science as Professor Lowell has done? Let the still voice of conscience answer! Emerson says that alone all men are conscientious. If so, we shall have a little more toleration, and fair dealing, and less of this clique and faction business, by which a man who is not in the ring never can get justice or fair consideration. Of all the evils which afflict American science to-day the wide-spread tendency to partizanship and factionism and the resulting total disregard of the ultimate interests of truth, is undeniably the worst. As the truth is difficult to discover, and in the end will be found only among the errors of the wise, it is clear that every cause must be heard, and we must preserve a tolerant and open-minded attitude towards all contemporary work. Recent revolutions in all branches of science have been so great that no man knows, and no honest man will attempt to predict, what a day may bring forth.

SCIENTIFIC BOOKS

Annals of the Astronomical Observatory of Harvard College, Edward C. Pickering, Director. Vol. LVIII, Part III. Observations and Investigations made at the Blue Hill Meteorological Observatory, Massachusetts, U. S. A., in the Year 1905, Under the Direction of A. LAWRENCE ROTCH. With Summaries of Observations for the Lustrum and for the Twenty Years, a Discussion of them, Memoirs on the Meteorology of Total Solar Eclipses and on the Eclipse Shadow-Bands, and a Bibliography. 4to. Cambridge, 1908. Pp. 147-228. Pls. I-II.

The same. Vol. LXVIII., Part I. Exploration of the Air with Ballons-sondes at St. Louis, and with Kites at Blue Hill. By H. HELM CLAYTON and S. P. FERGUSON.

The work of the Blue Hill Observatory, whether it be the routine observations or the original investigations carried on by members of the staff, has always been of the highest grade of accuracy, interest and importance. The publications which have dealt with this work, both those in the regular series of the *Annals of the Harvard College Observatory*, and those which have appeared in various scientific journals, make up a list which includes some of the very best contributions to meteorology. Without Professor Rotch's generous and whole-souled support of the Blue Hill Observatory, and without the steady, careful and devoted work of himself and of his assistants, American meteorology would not occupy the important position in the world of science which it does occupy to-day. This statement can be made with perfect truth, and without in any way whatever disparaging the excellent work which has been, and is being, carried on by the United States Weather Bureau.

To review, adequately, the two volumes now before us is wholly out of the question in a journal in which meteorology necessarily has to occupy a subordinate position. We can only note the most important matters presented in these publications.

1. The first number of the *Annals* contains the 1905 observations, both surface and upper air, together with summaries of the observations at the ground during the preceding lus-

trum and the twenty years. As Professor Rotch points out in his introduction, there is probably nowhere else in the United States so homogeneous a series of observations, due to unchanged exposure of the instruments and methods of reading them. This, alone, gives these records considerable importance. The principal climatic features of the twenty-year period are, therefore, at this time appropriately indicated by Mr. A. L. Wells. Mr. H. H. Clayton gives an interesting summary of "The Meteorology of Total Solar Eclipses, including the Eclipse of 1905." Eclipse meteorology may almost be termed a meteorological curiosity, for total solar eclipses are infrequent, and their effects are not far-reaching, long-lived, or important. *Practically*, eclipse meteorology is therefore unimportant. *Theoretically*, however, there is much of interest in the subject. Mr. Clayton's paper gains much in general usefulness because of his bibliographic notes. His summary of results brings out the fall of temperature during total solar eclipses, with the notable fact that, in the free air and over the ocean, the time of minimum temperature occurs almost at the time of totality, while over the land surfaces the minimum temperature usually lags fifteen to twenty minutes after totality. A low vapor tension about the time of totality; a diminished wind velocity; an outflow of the "eclipse wind," and a maximum of pressure, all indicate a descent of air, are all phenomena connected with anticyclones. The author is firmly of the belief "that a cold-air cyclone is generated by the fall of temperature during an eclipse, and that the phenomena . . . are all results of this cyclone." The final paper in the first volume is one on "Eclipse Shadow-Bands," by Professor A. L. Rotch. In this the author gives the results which he has collected during many years, especially those obtained during the eclipse of August 30, 1905. "The inference from all the data collected is that the shadow-bands are produced by the diminishing crescent of light penetrating air strata differing in their thermal and hygrothermic conditions, and therefore in their refracting power."

2. More general scientific interest will probably attach to the second volume, which deals

with the results and methods of the pioneer work in *ballon sonde* meteorology, carried out by Professor Rotch in the United States with the financial cooperation of the Louisiana Purchase Exposition, and, later, of the Smithsonian Institution. Most men of science in this country probably already have a general idea of the importance of this investigation, and those who are able to keep up with meteorological literature know how widely this work has been discussed, and with what a warm welcome the results have been received abroad. If we mistake not, SCIENCE has contained several notices of this work. Mr. S. P. Fergusson contributes the first portion of the volume, on the "Apparatus and Methods," in which a brief account is given of the historical development of this kind of investigation. (It may be recalled that on March 21, 1893, MM. Hermite and Bésançon first employed a special instrument, recording time, pressure and temperature, which was sent up with a *ballon-sonde* in Europe.) "The Method of Reducing the Data" is discussed by Mr. H. H. Clayton. Then come a series of tables in which the records are given *in extenso*. "A Discussion of the Temperature and Wind," also by Mr. Clayton, follows. Particular interest attaches to the vertical temperature gradients, a subject which has been much discussed of late years, and which has important theoretical bearings. It appears that for all seasons the rate of decrease of temperature with increase of altitude above 2 km. increases up to about 8 km., then diminishes, and that there is an inversion in the gradient above 13-14 km., the well-known "isothermal stratum," whose existence was first established in Europe. Mr. Clayton contributes an interesting fact to the discussion concerning the cause of this isothermal layer. He suspects that a diminution in the northerly currents is characteristic of the region above 10 km., and that this may in part explain the phenomenon. The most frequent gradients in the lower air (0-1 km.) are the adiabatic gradients of dry air (0.9° - 1.1° C.) and of saturated air (0.5° - 0.6° C.). Inversions of temperature also show a maximum frequency in the lower stratum. Between 1,000 and 7,000 meters the prevailing

gradients are the adiabatic gradients of saturated air. The adiabatic gradients for dry air diminish rapidly from the ground up to 2 km., and are rarely observed between 2 and 4 km. Above 4 km. they increase in frequency and reach a decided maximum between 8 and 9 km.; then decrease again in frequency to almost zero between 11 and 15 km. The upper parts of the two zones of maximum frequency of the adiabatic gradients of dry air are regions of maximum cloud frequency, the one zone being characterized by a prevalence of cumulus clouds, and the other by a prevalence of cirrus clouds. Cold waves, the author believes, are inclined strata of descending air, felt first at the earth's surface, and successively later at greater altitudes. The following statement is of special interest (pp. 81-82):

At each successive rise of 2 km., the position of the area of cold in the anticyclone, and the position of the area of warmth in the cyclone, shifts northward in a semicircular course around the centers of the anticyclones and cyclones, until at 10 km. the area of cold is in the northern portion of the anticyclone, and the area of warmth is in the northeastern portion of the cyclone.

Our notice is already unduly long. We can but mention a final paper, by Mr. Clayton, on "The Distribution of the Meteorological Elements around Cyclones and Anticyclones up to 3 Kilometers at Blue Hill," an important contribution to a discussion to which our author has already devoted much time during recent years.

It is a pleasure to call the attention of the readers of SCIENCE to these valuable memoirs. Although the interest in meteorology is not as active or as widespread in this country as it should be, we feel sure that we are expressing the sentiments of a large number of our fellow-workers in science when we congratulate Professor Rotch, and his colleagues, most heartily, on their latest achievements in the field of meteorological research.

R. DEC. WARD

Bulletin of the American Museum of Natural History. Twenty-fourth Volume.

This large volume is only slightly less

formidable than its predecessor, and maintains the standard of excellence, the expression of *authority*, and the high typographical precision which has always distinguished this annual contribution to zoological literature. There are thirty-four separate articles—covering 647 pages, with thirty-three plates, one hundred and fifty-three text figures, which describe and illustrate two families, fifteen genera and subgenera, and two hundred and eleven species and subspecies “first described or renamed in this volume.”

The initial impression made by an examination of the *Bulletin* is that of a voluminous contribution to systematology, in harmony with the first impulses that originated the work. Generalized articles are this year almost completely absent, and the rigorous, more technical requirements of science are only in a few places forgotten, as in some animated verbal excursions by Professor Wheeler, and the admirable historical review of the “North Atlantic Right Whale and its Near Allies,” by Dr. Allen.

Mammalogy furnishes nine articles, ornithology two, entomology fourteen, vertebrate paleontology seven, invertebrate paleontology one, botany one. A serial notice of the articles as they succeed each other, with the most moderate epitomization of their contents, or, a reference to them by titles solely, will acquaint all interested with their nature and bearings.

In article I. Dr. J. A. Allen offers a “List of the Genera and Subgenera of North American Birds” according to article 30 of the International Code of Zoological Nomenclature. The subject is one identified with the author's name whose work in codification is historic. The work is confessedly intricate, and an inspection of the paper shows a master's hand. Dr. Allen remarks:

“Our present fabric of nomenclatural rules has been of slow growth. Without going into detail, it may be noted that prior to 1842 there was no official code of nomenclature; each author was his own arbiter, not only as to the sources from which names might be taken and to whom they should be accredited, but in respect to the sense in which they should be employed.

There seems to be an argumentative intention in the paper, and it might not inconsiderately be classed as a polemic on the topic of “*Elimination Versus the First Species Rule*.” A short but very interesting paper by Professor Whitfield on “Carboniferous Fossils and Semifossils from the Arctic” follows. The most important conclusions are the eminent expression of an American Coal Measure fauna in the north, and the determination of a new inarticulate brachiopod, *Arctitreta*. Professor T. D. A. Cockerell contributes two articles on the insect fossil fauna and fossil flora of Florissant, Colorado. A copy of the rare Pennant's “*Indian Zoology*” has recently been exhumed in the library of the American Museum, and furnishes a topic for Dr. Allen in article V. He remarks of it, that:

Like the copy in the British Museum, described by Newton, it lacks the original wrapper, and has no title page, and in all probability never had any, it being the first fasciculus of a work of which no more was published.

The plates are uncolored. Articles VI., VII., VIII., IX. and X. embrace characteristically elaborated descriptions of the ants of Porto Rico, the Virgin Islands (Culebra Vieques), of Jamaica, of Moorea, Society Islands, and of the Azores, the latter based on very insufficient and vestigial material.

Roy C. Andrews, a new author on the pages of the *Bulletin*, gives some new measurements of the North Atlantic right whale secured from the stranded Amagansett, L. I., specimen, which “exceeded in size the largest hitherto recorded.” “A Four-horned Pelycosaurian from the Permian of Texas” is described in article XI. by Dr. Matthew, which is significantly called *Tetraceratops*, a new genus, whose “most noticeable feature is the presence of *two pairs* of prominent bony bosses or ‘horns,’ one rising from the premaxillaries, the other from the prefrontals.”

This paper is succeeded by an important diagnosis of a new family of armored dinosaurs—the Ankylosauridae—by Barnum Brown, the striking features of which are the “sculptured, plated skull; large flat or low-ridged body plates, some of which are united

as a shield; short spined vertebræ with parapophyses never rising above the centra; posterior ribs coossified to vertebræ."

In article XIII. Roy E. Andrews describes a new species of cetacean, *Mesoplodon bowdoini*. Article XIV. contains "Notes on Two Porpoises from the Pacific," by John Treadwell Nichols. "A Revision of the American Eocene Horses (*Hyracotheres*)," by Walter Granger is a very valuable study conducted along morphological lines with much care. In speaking of distribution the author says:

The horizon of their greatest abundance is the Wasatch, especially the Wasatch of the Big Horn Basin, where they predominate over all other forms, with the possible exception of *Systemodon*, a very closely related genus.

He remarks that "One of the progressive characters of the Eocene Horses is the gradual molarization of the second, third and fourth premolars in both the upper and lower jaws," and the concluding section of his paper deals with "Premolar Development." This article precedes a paper by President Osborn on "New Fossil Mammals from the Fayûm Oligocene of Egypt," wherein some anomalous characters indicative of new family relations are recorded. The paper is preliminary, and reports that the expedition into the Fayûm region of northern Egypt in the winter of 1906-7 obtained a collection of about 550 specimens, "including more or less complete remains of most of the fossil forms so far known to be characteristic of this region."

A comprehensive paper, dealing with the history, the relationships and nomenclature, the geographical distribution and external and osteological characters of the "North Atlantic Right Whale and its near Allies," by Dr. Allen, arrests both eye and attention in the middle of this big *Bulletin*. The article possesses a notable strength, and seems to be a compressed result of laborious and extended previous study. It is excellent reading, and reveals the solid emphasis of authority. It comprises about fifty pages, with six contributory plates.

The ornithologist W. De Witt Miller reviews the beautiful manakins (genus *Chiroxi-*

phia) in article XIX. The genus "is a small group difficult to define by structural characters alone, on account of the great variations in external form among the several species, but well characterized by the coloration of the adult males, all of which have a blue black and a red or yellow crest." Mr. Miller has prepared a most instructive map of the geographic range of the genus which is new, and original for the birds discussed.

Embracing articles XX. and XXI., and covering 139 pages Professor W. M. Wheeler elucidates the taxonomy and the economy of the Honey Ants, and describes the ants of Texas, New Mexico and Arizona. It is difficult at this point to specialize. The subject is engrossing and the author brings to the discussion an extraordinary wealth of experience, observation and reading. Comment is naturally impossible except by myrmecologists, but the most inexperienced eye can not fail to linger over many paragraphs descriptive of the positively amazing economies of these insects, especially such differentiated abnormalities as the "nepletes," individuals who become "living repositories for the surplus honey of the colony, which in time of need answers the purpose of the full honey-combs of the bee."

Article XXII. describes the Peary caribou, differing from its nearest allies *R. groenlandicus* and *R. arcticus* "in being much smaller, taking the skull as a basis of comparison, the females of *groenlandicus* and *arcticus* being as large as the males of *pearyi*." The paper is by Dr. Allen.

Dr. Allen also furnishes article XXIII., which discusses the rare *Solenodon paradoxus* Brandt from San Domingo. These notes are based upon specimens collected by A. Wyatt Verrill, and the collector's remarks "based on actual observation of the animal in life," are probably the most trustworthy description of its habits known.

Mr. Verrill says:

In its habits the *Solenodon* resembles a hog, rooting in the earth and cultivated ground, tearing rotten logs and trees to pieces with its powerful front claws, and feeding on ants, grubs, insects, vegetables, reptiles and fruit, and at times

proving destructive to poultry. On several occasions it has been known to enter the houses in search of roaches and other vermin, and has been captured in rat-traps.

It is strictly nocturnal, and spends the day in caves, holes in the coral limestone rocks and in hollow trees and logs. It is a slow, stupid creature. It is unable to run rapidly, but shambles along with the zigzag, sidewise motions of a plantigrade. It is, doubtless, owing to this that it obtained the native name of "Orso" (bear).

Article XXIV. by S. A. Rohwer is on "A Fossil Larval Wasp"; the same author contributes article XXV., a discussion of the fossil saw-flies (Tenthredinoidea) of the Florissant Shales. Article XXVI. comprises notes on the skull of *Lysorophus tricarinatus* Cope, by E. C. Case, of which the author remarks, that

Were it not for the extreme specialization of this limbless Gymnophiona-like form it would occupy almost exactly the transitional position between the amphibians and reptiles.

Article XXVII., by Dr. Matthew, particularly describes the osteology of *Blastomeryx*, and discusses the phylogeny of the American Cervidae, in which the writer asserts that

Blastomeryx proves to be a very primitive deer, approximately ancestral to the American Cervidae, and derivable in its turn from the Oligocene genus *Leptomeryx*, whose relationship to the Cervid phylum had not been suspected. We are thus enabled to trace the ancestry of the American Cervidae back to the Oligocene, by successive stages known from the entire skeleton, and not merely from the inadequate evidence of teeth and jaws.

Article XXVIII. is by Filippo Silvestri, on the Myriopoda from Porto Rico and Culebra; article XXIX. consists of "Mammalogical Notes," by Dr. Allen; article XXX. is a further contribution by S. A. Rohwer on the saw-flies from Florissant, Colorado.

President Osborn contributes article XXXII. on "New or Little Known Titanotheres from the Eocene and Oligocene." Professor Wheeler discusses the "Ants of Casco Bay, Maine," in a very attractive paper, filled with descriptions of predatory expeditions, slave-making hunts and colonial devices and aspirations, which are picturesque enough in themselves, and are treated with

very circumstantial seriousness. Professor Wheeler in this paper engages again in an extended debate on the origin of slavery (*dulosis*), and social parasitism in ants, wherein we are told that Wasmann has repeated Professor Wheeler's experiments on the formation of colonies, has corroborated them, and that "an outstanding difference in interpretation" only now remains between these distinguished naturalists.

The volume concludes with a paper by Dr. Allen, on "Mammals from Nicaragua."

L. P. GRATACAP

SPECIAL ARTICLES

RADIUM IN SPIRAL NEBULÆ AND IN STAR CLUSTERS

IN consequence of a prolonged study of the relation to celestial spectra of the spectrum of radium emanation as published by Sir William Ramsay and Professor J. Norman Collie,¹ I announced on January 19, 1905, the principle of "critical radioactivity" or the transformation of the chemical elements at critical pressures and temperatures in the stars. This explosive transformation of the elements at critical physical states, occurring in the heavenly bodies, I have named "radioaction," in order to distinguish it from ordinary radioactivity.

Radioaction, hypothesis α , was announced as a tested theory in the face of Rutherford's statement:

The transformation of matter occurring in the radio-elements is, on the other hand, spontaneous, and independent of temperature over the range examined.²

It was also in challenge of the natural inference to be drawn from the statement of Runge and Precht, made at the close of their account of the measurement of the lines of the radium spectrum:

Concerning all strong radium lines, it may be affirmed with certainty that, according to our measurements, they are not found among the measured solar lines of Rowland.³

Changes in pressure and temperature are, on all sides, said to produce no marked changes

¹ *Proc. Roy. Soc.*, 73, p. 470, May, 1904.

² "Radioactivity," first edition, p. 350.

³ *Ann. der Phys.*, 317, 412, June, 1903.

in radioactivity, and, moreover, the precise measuremental matching of the lines of the radio-elements with celestial lines is universally held to be essential to their identification in the heavenly bodies. In direct violation of these views, radioaction, hypothesis α , was proposed and confirmed. A second principle, hypothesis β , which need not now be described, was also used from the first, and thence a set of principles of interpretation of celestial phenomena, deduced and verified, which, for brevity, I designate the theory of radioaction.

The theory was originally verified with difficulty by constantly summoning the calculus of probabilities to its aid, and kept from publication on account of obstacles encountered in presenting the vast mass of evidence.

Radioaction, or critical radioactivity, I have used the last five years, as a principle explanatory of many strange and hitherto inexplicable phenomena, of inorganic evolution. I have found radioaction to be an essential factor in cosmic evolution. By means of it I have been able to predict the necessary character of many phenomena peculiar to the morphology, photometry, spectroscopy and electro-optics of nebulae, stars, sun and comets. Excepting two papers on this subject, read before the American Philosophical Society, one, "Universal Celestial Radioactivity," January 20, 1905, and the other, "Radioactivity in Solar Phenomena," April 14, 1905, both as yet unprinted, I have contented myself, of necessity, with the accumulation of proofs of the theory, until its presentation to the public in the form desired should be feasible.

Lately, however, the data for direct confirmation of this theory have come so freely to hand that I have decided to lay aside, in part, the ideal of aiming to present, as a unit, my theory of radioaction, with all its wide ramifications and interesting consequences.

Recently Mr. A. T. Cameron and Sir William Ramsay have remeasured the spectrum of radium emanation, and Professor E. Rutherford and Mr. T. Royds have also brought to bear all the refinements of physical accuracy upon the same problem; so that now there is

available a body of information of the highest value concerning this spectrum.

Reflecting upon the use of this material, my theory suggested an investigation which resulted in a very simple and decisive confirmation of radioaction. This first and peculiar confirmation, due to the later determinations of the spectrum of radium emanation, I reserve for appropriate publication.

It was on April 26 of this year that I received Lick Observatory Bulletin, No. 149, recording the work of Dr. E. A. Fath on the "Spectra of Some Spiral Nebulae and Globular Star Clusters." This bulletin permitted me, at once, to establish the fact that the absorption spectrum of radium emanation was present in this great nebula of Andromeda, and in other spiral nebulae, and likewise present in the star cluster of Hercules (probably along with one line of radium), and in two other star clusters. It also came out clearly that the radium series of elements was not disclosed by the spectrum of the Spiral Nebula N. G. C. 1068. Finally, on referring to the observations of *bright* lines in the nebula of Andromeda by Sir William Huggins and Lady Huggins, I was gratified, but not surprised, to find that these lines were plainly identifiable as lines of radium emanation.

It has seemed proper to attempt here only a brief examination of the facts, since the present conditions prohibit a completely tabulated and detailed discussion. First, I must say that it is with no little satisfaction that I find myself reviewing this piece of superb work issued under the direction of Professor Campbell. For, in my study of radioaction, during these five trying years, I have again and again noted Professor Campbell's accurate and painstaking description of unusual celestial phenomena, his balanced review of the work of others (including the celebrated thrust concerning the Purkinje phenomenon), and his remarkable insight into the value of anomalous observations, and of mooted suggestions for their explanation.

The telescope used by Dr. Fath in the work was the celebrated Crossley reflector, with a specially designed spectrograph attached. The difficulties mastered were of the first order.

The total exposures ranged, in the case of the Andromeda nebula, up to $18^h 11^m$, accumulated during three different nights, yielding fourteen lines; and in that of N. G. C. 7831 up to $22^h 22^m$, accumulated during seven nights and yielding two lines. Of the accuracy of the wave-length determinations Dr. Fath says:

When measuring known spectra the wave-lengths of the lines usually come within 5 or 6 Angström units of the correct value, although occasionally a larger deviation is found. Thus the third figure given may usually be considered correct.

In the identification of the lines, it is possible that Dr. Fath was unconsciously influenced by Scheiner's emphatic assertion:

It is thus proven that the Andromeda Nebula exhibits a spectrum of the class IIa, or further, that the greater part of the stars composing the nucleus of this nebula belong to the second spectral class.

The inference that "the spectrum is of the solar type" will, I think, be found to be too hasty. The absence from Dr. Fath's plates of any indication of the bright lines of Huggins was, indeed, quite misleading. Bright lines will, undoubtedly, be photographed, later, in the great nebulae of Andromeda.

The following table records in the first and second columns the wave-lengths and intensities of the lines in the Andromeda nebula as measured by Dr. Fath, in the third and fourth columns the identifications with the spectrum of radium emanation suggested by myself, and

in the last column, the identifications proposed by Dr. Fath.

The wave-lengths of the lines of the radium emanation are taken from the table of Rutherford and Royds.* The second number in the intensity column of radium emanation records, for line No. (1), the value by "photograph 3," and for line No. (7) the "visual" estimate. It should be borne in mind that for the nebular lines "the third figure given may usually be considered correct." Both schemes of identification are suggested by theory. Dr. Fath's is supported by the theory that the Andromeda nebula is a cluster of solar stars. No conclusive review has been given of such theory. From his own use of Bohlén's parallax of this nebula, he infers that "the 'star cluster' theory is not very satisfactory." He, however, necessarily recurs to solar lines and "groups of lines," selected, chiefly, on the basis of mere matching.

My own identification assumes the theory that all nebulae whatsoever are electrically luminescent results of radioaction in the associated "stars." This theory has repeatedly been found to be confirmed in accounting for analogous phenomena. It explains why, now bright lines, now dark lines are observed in this nebula. It suggests the kind of chemical elements whose traits are here to be found. It accounts for the variability of this nebula in 1885, by asserting that the "star," variable through radioaction, holds the secret of cosmic evolution. Finally, it banishes the necessity for imagining a lawless collision of a pair of stars for generating spiral nebulae.

The general agreement in wave-length of this single radio-element with all but one of the nebular lines must be given weight. There are three lines, Nos. (8), (9) and (10), which, both in the spectrum of the nebula and in that of the emanation, follow consecutively. Moreover, their intensities, all conditions considered, are quite consistent with the hypothesis of identity. There is no necessity for reminding spectroscopists that, on account of the wide variation of intensity with changes in excitation, fair agreements in such a case

TABLE I

No.	N. G. C. 244		Ra. E.		Identification by Dr. Fath.
	A	Int.	A	Int.	
(1)	8740	1/2	8739.9	7/1	Solar group, center λ 8735
(2)	8826	1/2	8818.0	2	Solar group, center λ 8830
(3)	8970	1/2	8967.6	4	Solar group, center λ 8972
(4)	8984	10	8983.8	3	Calcium K
(5)	8998	10	8971.9	9	He and Calcium H
(6)	4080	2	4055.7	1	Mean of Solar $\left\{ \begin{array}{l} \lambda 4046 \text{ Fe} \\ \lambda 4064 \text{ Fe} \\ \lambda 4072 \text{ Fe} \end{array} \right.$
(7)	4188	2	4166.8	20/1	Solar group, center λ 4150

* *Astrophys. Jour.*, 9, 150.* *Phil. Mag.*, Ser. VI., Vol. 16, p. 317, Aug., 1908.

count toward the probability of identity, while disagreements do not count against it. I also call attention to the practical agreement in wave-length and in grade of intensity of lines Nos. (4) and (5). A detailed discussion of the probability of identification of each line seems unnecessary here. Admitting the uncertainty in the measurements of the nebular lines, considerable weight can fairly be given to general agreement. I have nothing to say to the spectroscopist who insists on the absolute matching of lines in wave-length as the final test of "identification" of all celestial spectra.

If radioactive outbursts determine both the bright lines and the dark lines, and account for the appearance and disappearance of the former, the celebrated bright lines of Huggins may supply a test of the theory. In the following table, the first column contains the estimated wave-lengths of *bright* lines observed in the nebula of Andromeda by Sir William Huggins and Lady Huggins,* the second and third, the corresponding radium emanation lines and their intensities observed by Ramsay, Collie and Cameron, and the fourth and fifth, those observed by Rutherford and Royds.

TABLE II

No.	N. G. C. 224 A	Ra. E.		Ra. E.	
		A	In.	A	In.
(1)	580	580	(persistent)	583	1
(2)	543	543	faint	539.5	0
(3)	538	537	2	537	0
(4)	511 (a group of 4 or 5 lines)	508	2	{ 512 509	{ 2 10
		{ 498	2	{ 496	1
(5)	495 (a group)	{ 494	2	{ 495	1
		{ 492	3	{ 492	1
(6)	476	477	2	477	1
		{ 458	3	{ 458	1
(7)	455 (suspected)	{ 455	2	{ 455	0
		{ 452	1	{ 451	1

For the sake of simplicity of statement, and so as to conform to the grade of accuracy of the estimates by the astronomical observers, only the first three figures of the wave-length measurements of the physicists are given. The general agreement is very satisfactory.

* "An Atlas of Representative Stellar Spectra," p. 125.

Line (4) is "a group of 4 or 5 lines," and becomes so, first, because both lines concerned are relatively intense, and secondly, because, as astrophysicists well know, an intense line is at times likely to break up into a group. Line (5) is evidently "suspected" because of decreased sensitiveness of the eye for this region, and because of the low intensity of the three lines concerned.

A more detailed discussion would, I am sure, place this identification beyond any possibility of doubt, but also carry me farther into the subject than I had planned. It is worth while remembering, however, that admitting radioaction as receiving confirmation in other celestial bodies, it may here, with some weight, predict, as it does, the fact of bright lines, their variability, and their character as radioactive products. The two groups (4) and (5), examined on the basis of the strictest principles of electro-optics would alone prove identity, and their testimony is certainly not weakened by the other lines. The difficulties conquered by the famous chemist, and the masterful physicists in furnishing the measured lines of the rare radium emanation are certainly always most gratefully to be acknowledged; and the refined and conscientious work of Sir William Huggins and Lady Huggins in independently examining these evanescent bright lines of the nebula of Andromeda through the weary nights of many successive years, is, I hold, not only emphatically verified by this identification, but their faith in its high and lasting value adequately commended by the result.

The spectra of five other spiral nebulae were likewise photographed by Dr. Fath at the Lick Observatory, and four of these, consisting each of but from one to three lines, disclosed, in each, identity with radium emanation in one to two lines. The spiral Nebula N. G. C. 1068 discloses, as stated, no known radio-element of the radium series, unless the bright $\lambda 8733$ and $\lambda 8878$ be helium lines. It is, however, practically certain that the celebrated main nebular lines characterizing the spectrum of this object, and of others like it, are due to radio-elements yet to be identified.

The spectra of star clusters next claim at-

tention. The spectrum of the Hercules cluster N. G. C. 6205, obtained by Dr. Fath is quite remarkable. He says:

It is composed of a number of parallel strips of different intensities, containing a few faint absorption lines. Each strip is probably the spectrum of a single star, or group of stars. No two strips contain the same set of lines. Four of the strips were strong enough to be measured.

In the following table the first column states the number of the strip, the second the wave-length, the third the intensity, the fourth the corresponding wave-length of radium emanation, the fifth its intensity.

TABLE III

Strip.	N. G. C. 6205		Ra. E.	
	λ	In.	λ	In.
(2)	3935	3	3933.3	3
(1)	3966	3	3971.9	9
(2)	3970	3		
(4)	4118	2	4114.9	7
(1)	4294	1	4308.4	2
(4)	4302	1		
(3)	4340	1	4340.8	50 Ra.
(4)	4463	1	4460.0	10
(2)	4790	1	4796.7	1

It will be noticed that to the single line of strip (3), I have assigned the radium line of high intensity, although an emanation line λ 4340.8, intensity 7, also exists. I think the evidence for the existence of radium emanation in this cluster is sufficient to make discussion unnecessary. It will be seen that for the different strips the lines vary. Difference of excitation, due to the difference of physical state of each star, completely accounts for the variation. In the globular clusters N. G. C. 7078 and 7089, the hydrogen lines are, as Dr. Fath indicates, probably evident from $H\beta$ to $H\delta$. Radium emanation must, however, also claim λ 4102.2, λ 3971.9 and λ 3933.3 in each of these star clusters.

It may not be amiss to venture a few suggestions:

1. Each photograph or observed spectrum of a nebula, star cluster, or bright line star, should be treated as a separate entity in publication; otherwise the successive changes in given lines are averaged out of existence.

2. If possible, the spectrum of the nebula of

Andromeda should be repeatedly photographed.

3. It should be the aim to photograph as soon and as effectually as possible the spectra of the short-period variables in globular star clusters even if at first integrated results, both as to stars and as to periods, are obtained.

In conclusion, I must state that I am quite conscious of the incompleteness of this discussion. Indeed, it is the manifest complexity of the subject that has made me, hitherto, recoil from a preliminary application of the theory for publication. Radium has been known for at least ten years as a terrestrial element, its spectrum has been repeatedly determined and compared with the spectra of the heavenly bodies, and yet up to the present moment there has been published, so far as I know, no demonstrative evidence concerning its existence in the heavens. On the contrary, careful comparisons made by chemists, physicists and astronomers, have apparently shown that the spectra of radium and radium emanation, the element into which radium is at once transformed, are not identifiable with stellar spectra. It is, therefore, significant that the identifications here made were suggested by the theory of radioaction.

MONROE B. SNYDER

PHILADELPHIA OBSERVATORY,

OBSERVATIONS ON THE SHIFTING OF THE CHANNEL OF THE MISSOURI RIVER SINCE 1883¹

THE radical changes which annually take place in regard to the position of the Missouri River channel and the great loss of property occasioned by the same have presented a problem worthy our careful consideration. In addition to the scores of farms which are washed out annually the railroads suffer greatly by having their roadbeds destroyed. Hence, this becomes an economic problem of vast proportions.

In the following chart we have represented a portion of the river valley near the village of Peru, including ten or twelve miles of the river bed. The upper dotted line represents

¹Read before the Nebraska Academy of Sciences.

the position of the western bank of the river in 1883 and the continuous line represents the position of the western bank in 1903. Locating the letters X , X' and X'' at the intersections of the old and new channels; then, all the territory between the old channel and the new and between X and X' has been washed from the Nebraska side, while the corresponding territory between X' and X'' has been

added to the Nebraska side. From the point a' to the point b is 5,000 feet, all of which has accumulated in twenty years, or an annual increase of 250 feet. The actual increase has varied, however, from 50 to 500 feet annually. At no time during the twenty years has the channel between X' and X'' encroached upon the Nebraska shore. On the other hand, the river has annually encroached upon the Nebraska shore between the points X and X' for the same period of time.

The river, at Peru, has a descent of about eleven inches per mile and the rate of flow varies greatly. During high waters, in the

spring months when the principal washings take place, it is found that at the points a and a'' the water along the western shore has an elevation of 20 to 50 inches above that of the eastern shore, directly opposite. This piling up of the water along the western shore causes a part of the water to turn up stream, producing immense eddies at times a mile or more in circumference. The principal part of the water, however, is directed down the stream diagonally toward the opposite shore where the water is at a much lower level.

The most rapid erosion usually takes place in early spring at the time the ice breaks in the river; frequently, however, the June freshets play great havoc with the banks. The rate of erosion at the upper half of the curve is not the same as the deposition at the lower end of the same curve. For example, in twenty-four hours there may be from ten to twenty-five acres washed from the shore aX' , while the accretion to the shore line $X'a''$ is very gradual. As the channel encroaches upon the upper portion of the curve it shifts farther from the lower portion. As the main channel recedes from the shore the space is usually transformed into eddies which supply the necessary conditions for depositing large quantities of detritus. In the shifting of the channel the symmetry of the curve is usually quite well preserved with reference to upper and lower halves.

Another factor enters our problem: the general direction of the river is southward and it is gradually flowing over larger and larger circles of the earth. Hence, the water piled up at a starts off in the direction of X' with the impetus given it from the piling up of the water. This rebounding force is counteracted by the influence of the rotary action of the earth by the time the water reaches X' ; so, beyond the point X' the rotary action of the earth becomes the dominant factor and the water gradually falls behind until it again cuts the western bluffs at a'' . Furthermore, the height to which the water is elevated at a determines, in a large measure, the distance aX' while the distance $X'a''$ determines the height to which the water is piled up at a'' .

Hence, by locating the points a , a' and a'' one can determine, with almost mathematical precision, the land next in order to be removed and the location of the new deposit. Again, sooner or later points a and a' will coincide and lines aX' and $a'X''$ will coincide.

The dotted line yy' represents the manner of washing since this article was first prepared. The railroad and station at Barney have been washed out and a new station has been located farther to the southwest as indicated on the chart.

We have taken simply one section of the river as an illustration; but, after studying in detail a large number of these curves and after studying in a general way the entire river bed from Sioux City to the southern border of Nebraska we believe no exception to the chart can be found. In applying these principles to the washings of the eastern bank of the river all positions would be reversed.

The effort to hold the channel of the river under the bridges at Omaha and Nebraska City has greatly influenced the recession of the series of curves below each bridge.

We may, therefore, summarize the following points:

1. That the Missouri River channel is methodical in its shiftings.
2. The location of the new channel and the new deposit may be determined beforehand with mathematical precision.
3. There is a recession of the series of curves down stream.
4. The channel cuts the western bluffs at more or less regular intervals.
5. At no point does the river encroach upon the eastern bluffs.

NEBRASKA STATE NORMAL SCHOOL,
PERU, NEBR.

THE PROPER NAME OF THE AMERICAN EEL ANGUILLA ROSTRATA (LE SUEUR)

THROUGH an error in recording the date of publication the common American eel has been given a later-bestowed technical name and the author of a prior name and description has been denied the honor of first naming the American species.

In the *Journal of the Academy of Natural Sciences*, Philadelphia, No. 5, Vol. I., p. 81, C. A. Le Sueur described the common American eel under five specific names, viz.: *rostrata*, *Bostoniensis*, *serpentina*, *argentea* and *macrocephala*, all of which he erroneously placed under the genus *Muraena* of La Cepede.

Several months later C. S. Rafinesque, in *The American Monthly Magazine and Critical Review*, No. II., Vol. II., p. 120, described this eel under the name *Anguilla chrysypa* and *A. blephura*, and his note after the descriptions, "These two species of eels appear different from all the new species lately described by Mr. Lesueur, under the old name of *Muraena*, which belongs properly to a very different genus without pectoral fins," led me to look into the matter of the proper name for the American eel.

Rafinesque's name *chrysypa* has of late years been applied to this eel, authors citing 1821 as the date of publication of the journal in which Le Sueur's descriptions occur notwithstanding the fact that the numbers are plainly marked, No. 1, May, No. 2, June, No. 3, July, No. 4, August, and No. 5, September, 1817. From the dates and other marks on these numbers it was evident that they were promptly printed, but having been informed that the journal had not been printed and published, as dated, I addressed a note to Mr. Witmer Stone, of the Philadelphia Academy of Natural Sciences, and quote his courteous and satisfactory reply, written March 17, 1909.

My dear Mr. Bean: Such data as I have accumulated on dates of issue of our publications relate to our Proceedings only & I had little hope of solving the problem contained in your letter. Fortunately I asked Mr. Wm. J. Fox our Asst. Librarian if he knew of any clew and he suggested looking in a bound volume of manuscript letters from Thos. Say to Rev. J. F. Melsheimer, from which he had published extracts some years ago in *Entomological News*, as he thought there was some allusion to sending parts of the *Journal* to Melsheimer. Curiously enough the first mention of the matter that we found was as follows, in letter dated November 6, 1817, "yesterday I sent you the *Fifth* part of the *Academy's Journal* and tomorrow I will send you the *sixth*."

The fact that the sixth part was out or was daily expected would go far to prove that the fifth part had been out about a month. Any way we know that it was issued by Nov 6, 1817, and are pretty safe in saying that October was the month of issue, no doubt the first week.

I am glad to have been able to settle this matter for you, but the credit is due to Mr. Fox not to me.

Sincerely yours,

WITMER STONE

The proper technical name for the common eel of eastern North America is *Anguilla rostrata* (Le Sueur), described from specimens taken in Lakes Cayuga and Geneva, New York.

March 20, 1909

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION L—EDUCATION

THE Baltimore meeting of Section L showed that this new section is growing in strength and usefulness. The section's policy of devoting each session to a single topic with set papers by invited speakers was tried and proved a great success. The section plans to devote itself to a scientific study of educational problems, and has appointed a committee to study the distribution of students in elective courses in college and report at the next meeting. This committee consists of Professor E. L. Thorndike, chairman, and Messrs. J. G. Bowman, George E. Fellows, Abraham Flexner, C. H. Judd, Frederick Keppel and C. R. Mann.

Officers for the coming year were elected as follows:

Vice-president—Dean James E. Russell, Columbia University, New York.

Member of the Council—President Charles S. Howe, Case School of Applied Science, Cleveland.

Member of the General Committee—Professor Charles H. Judd, Yale University, New Haven.

Member of the Sectional Committee—Hon. Elmer E. Brown, United States Commissioner of Education, Washington.

Vice-president John Dewey presided at all the meetings. The address of the retiring vice-president, Hon. Elmer E. Brown, dealt with great insight with the subject "World Standards of Education." This paper will be printed in SCIENCE.

The first session of the section was devoted to

a discussion of the United States Bureau of Education by Mr. W. Dawson Johnson, librarian of the bureau; Professor C. E. Elliott, of the State University of Wisconsin, and Mr. E. C. Moore, superintendent of schools, Los Angeles, Cal.

Mr. Johnson showed that the Bureau of Education is, on the one hand, the representative of the nation among the nations of the world; and, on the other hand, the representative of the common interests of the several states of the United States. As the representative of the United States in international intercourse its duty is, first, to study foreign educational experience with a view to selecting that which best fits American needs, and, second, to communicate to foreign countries official information regarding our own educational experience. This international intercourse may take the form of expositions, or congresses, or tours of investigation; it may require the direction of exchanges of professors and teachers between the United States and foreign countries, and of interchanges of students. With the development of international relations the work of the bureau as an office of international communication will become increasingly important, and as American conditions approximate those in European countries its service as a bureau of information regarding European educational experience will become more and more necessary. The duties of the bureau to the state departments are twofold: first, to relieve them of the duty of carrying on scientific investigations which may be carried on more economically or more efficiently by a central bureau; second, to carry on such other investigations as may facilitate and improve the administrative source of the state offices. The need of such work has been recognized in several states by the creation of special educational commissions. It has been recognized by the leading educational institutions and societies also. The growing recognition of the importance of such investigations and the advantages which a central bureau has for carrying them on must lead inevitably to the strengthening of the federal office. At present the bureau is being reorganized with a view to more adequate performance of its duties. The work of reorganization has begun in the library of the bureau. Little progress can, however, be made without larger appropriations by Congress, especially such appropriations as may enable the office to be of greater service to state school officers, educational commissions and legislative committees.

Professor Elliott pointed out that, notwithstanding the evident phenomenal advance which

all grades of education have made during recent years, there continues to exist such a spirit of general unrest and criticism of results as to preclude any feeling of satisfaction or security to serious students and workers in education. In the controversy between the educational progressives and the educational conservatives, society in general has assumed a defensible position and has accepted the program for progress as rapidly as the scientific soundness of that program was demonstrated. Our educational science in the past has been decidedly individualistic and the scientific problems of education have not been analyzed and delimited so as to permit the practical utilization of the collected results of accomplished investigation or the cooperative efforts of individual investigators. The real obstacle to progress has been the lack of coordinated and cooperative research. There is need to-day for scientific insight rather than emotional propaganda. Governmentally the center of gravity is shifting from the *state* to the *nation*. The traditional balance between state and federal activities has been overthrown and the signs of the times indicate the development of many new social functions, the full and adequate performance of which will depend upon the national government. Education, especially in its elementary and secondary stages, is the one subject of vital significance to human welfare, the scientific investigation of which the national government has not generously subsidized and encouraged. The expansion of United States Bureau of Education so as to enable it to serve as the central laboratory for American research in education, undertaking that now not undertaken, coordinating and organizing that now being attempted in a haphazard and incidental manner by individual institutions and societies, and causing it thereby to assume the leadership now so much needed for the real advance of American education seems to offer the greatest opportunity for the new federalism.

Mr. Moore's paper will be printed in full in SCIENCE.

At the second session of the section the topic "American College Education and Life" was treated by Professors Josiah Royce, of Harvard; Wm. North Rice, of Wesleyan; James H. Tufts, of Chicago, and Mr. Abraham Flexner, of the Carnegie Foundation for the Advancement of Teaching. These papers have been printed in full in SCIENCE for March 12 and 19.

Two joint sessions were held: one with the

American Psychological Association and the other with the American Federation of Teachers of the Mathematical and the Natural Sciences. At the first of these joint sessions the following program was given:

"Psychological Investigations that will help the Educator," by Professor E. A. Kirkpatrick.

"Studies in Number Consciousness," by Professor C. H. Judd.

"The Factors of General Ability," by Professor E. L. Thorndike.

"Homogeneous Content in the Measurement of Memory," by Professor C. E. Seashore.

"The General Effects of Special Practice in Memory," by Professor W. F. Dearborn.

"The Study and Treatment of Retardation," by Professor Lightner Witmer.

The report of this meeting has been published in the Proceedings of the American Psychological Association.

The other joint session with the science teachers was given up to a symposium on "The Problems of Science Teaching" by President Ira Remsen, Johns Hopkins University, and Messrs. Wm. T. Campbell, Boston Latin School; George F. Stradling, Northeast Manual Training High School, Philadelphia; John M. Coulter, The University of Chicago, and Lyman C. Newell, Boston University. The report of this meeting has been published in SCIENCE for April 30, in connection with the report of the American Federation, and also in *School Science and Mathematics* for March and April, 1909.

C. R. MANN,
Secretary

THE ENTOMOLOGICAL SOCIETY OF AMERICA

THE fourth meeting of the Entomological Society of America was held in Baltimore, December 30 and 31, 1908, in affiliation with the American Association for the Advancement of Science.

The meeting was called to order by the president, Dr. W. M. Wheeler, in the Eastern High School, at 11 A.M., December 31. Dr. Fernald read the report of the committee on nomenclature. Moved and carried that this report be received and printed and discussed one year later, and that this should be the general policy in dealing with these reports. This report is appended. The managing editor made an informal report upon the condition of the *Annals*. The president announced the death during the year of Dr. W. H. Ashmead, an honorary fellow; Dr. James Fletcher,

a fellow, and of three members, C. Abbott Davis, Albert V. Taylor and Alexander Craw. The president announced that he had appointed committees to draw up suitable resolutions upon the death of Drs. Ashmead and Fletcher. These resolutions are appended. The secretary read a communication from W. C. Wood suggesting action looking toward abolishing the tariff on insects. Moved and carried, "That it is the sense of this society that the duty on insects is objectionable and should be abolished." The matter was referred to the executive committee with power. Adjournment until 1:00 P.M.

At that time the meeting was called to order by the first vice-president, Dr. J. B. Smith. The report of the nominating committee was read, and in accordance therewith, the secretary was instructed to cast a ballot for the following officers, which was done:

President—Dr. Henry Skinner.

First Vice-president—Professor Herbert Osborn.

Second Vice-president—Dr. A. D. Hopkins.

Secretary-Treasurer—J. Chester Bradley.

Additional Members of the Executive Committee—Professor J. H. Comstock, Dr. W. M. Wheeler, Mr. E. A. Schwarz, Dr. John B. Smith, Rev. Professor C. J. S. Bethune, Professor Lawrence Bruner.

Member of Committee on Nomenclature to Serve Three Years—Dr. E. P. Felt, to succeed himself.

There being no further business, papers were read as follows:

Notes on a Lecanio-diaspid: W. C. O'KANE.

A. N. Caudell spoke briefly on a method that he had adopted for preserving types. He uses Riker mounts for this purpose.

Contributions to our Knowledge of the Host Relations of Ticks: W. A. HOOKER.

Discussion by Messrs. Skinner, Cooley, Viereck, Bruner and Miss Mitchell.

At 3 P.M. a joint session with Section K of the American Association for the Advancement of Science was held in the Eastern High School. Dr. J. B. Smith presided over the meeting. The following papers were read:

Investigations of Toxoptera graminum and its Parasites: Mr. F. M. WEBSTER.

This paper was published in *SCIENCE*, February 12, 1909, p. 278.

Discussion by Professor Washburn and Mr. Hayhurst.

On the Muscular System of Spiders' Legs: A. PETRUNKEVITCH.

A Note on the Habits of the Wall-bee, Chalcidodoma muraria: J. N. COMSTOCK.

This insect is very abundant at Dendera, Egypt, where it is covering the walls of the ancient temple, that have been unearthed, with its cement-like nests, rendering it impossible to read the inscriptions upon them.

Evolution and Adaptation in the Palpi of Male Spiders: J. A. NELSON.

To be published in full in the *Annals*. Discussion by Drs. Hopkins and Petrunkevitch.

Species, Varieties, Races, etc.: J. B. SMITH.

Discussion was postponed until after the reading of the next paper.

What is a Species? H. SKINNER.

Considerable discussion was evoked by these two papers, Messrs. Williston, Fernald, Felt, Viereck, Schwarz, Caudell and others participating.

Adjournment.

At 10 A.M. on December 31, the meeting was called to order by Dr. Wheeler, and the following papers read:

Death-feigning by Zaitia fluminea: H. P. SEVERIN.

Read by Professor Osborn.

Some Habits of Seed-infesting Chalcid Flies: C. R. CROSBY.

The Development of the Scent-pockets of Anosis: W. A. RILEY.

The pupal development of the scent-pocket or, as it is proposed to designate it, the muretheca, of the male Monarch butterfly was discussed. Its future position is indicated in the earliest pupa by the richness of the supply of tracheoles, indicative of the greater physiological activity in this region. Before pigmentation is apparent in the rest of the wing the muretheca stands out as a densely pigmented black disk overlapping vein Cu₁. Sections show that the androconia originate on the free surface of the upper wing membrane, which pushes out over the vein and later in pupal life folds on itself, giving rise to the pocket-like muretheca with its opening directed caudad. The structure of the androconal glands was briefly discussed.

The Tracheal Supply in the Central Nervous System of the Larva of Corydalis: WILLIAM A. HILTON, Cornell University.

There are three pairs of tracheal branches going to the brain and two to the subesophageal ganglion. The first thoracic has one pair and a median tracheal branch. All the other ganglia have one pair except the last or eighth abdominal,

which has, in addition to the branches similar to the others of the other ganglia, large branches from the system of the seventh ganglion. The connectives between the ganglia with the exception of those between the subesophageal and first thoracic and those between the seventh and eighth, get all of their branches from the ganglia above and below them. In the case of the first exception, there are two additional branches from the outside. In the case of the second, all of the connective supply comes from the system of the seventh ganglion. There is in each ganglion a very complete superficial and deep network of large and small branches. The tracheoles in the center of the ganglia are very numerous and very intricately woven together, but in no place was anastomosis found.

Observations on the Taxonomy of the Cecidomyiidae: E. P. FELT.

Recording and Mapping the Entomological Fauna of a State: FRANKLIN SHERMAN, Jr., State Department of Agriculture, Raleigh, N. C.

The 5 × 8 card is used as the unit, one side being rather closely ruled, while on the other side is printed an outline map of the state. Each insect is given a card—the divisions into orders, families and genera being indicated by appropriate guide-cards. All records as to place and date of capture are written in condensed form on the ruled side, while on the map a dot is placed for each locality. Gradually these records will define the different life-zones of the state and will indicate the approximate distribution of each species.

Rediscovery of the Bibionid Genus Eupetitus: D. W. COQUILLETT.

In 1834 Macquart described *Penthetria atra* n. sp. from a male specimen in Serville's collection, captured at Philadelphia, Pa., since which time the species has not been taken again until April 26, 1908, on which date Mr. H. S. Harbeck collected a female specimen at Germantown, a suburb of Philadelphia. Walker, in 1838, referred two British American specimens to this species, but there is no certainty that his identification was correct. Macquart's figure is very faulty. In 1838 Macquart erected a new genus, *Eupetitus*, for this species.

In the absence of the authors, or for other reasons, the following were read by title only:

Local Relations of Allied Species: S. A. FORBES.
On Some Terms used in Systematics: A. PETRUNKEVITCH.

A Colony of Mound-building Ants: E. A. ANDREWS.

The Conception of Unit-systems in Biology: W. E. RITTER.

Some Further Remarks on the Systematic Affinities of the Phoridae: C. T. BRUES.

A Monographic Catalogue of the Myrmarid Genus Camptoptera Foerster, with Description of One New North American Form: A. A. GIRAULT.
Studies on Aphididae II.: J. J. DAVIS.

A Newportia in Utah: R. V. CHAMBERLIN.

The report from the executive committee was read and, with all its provisions and recommendations, adopted.

The executive committee announced the election of the following fellows: Samuel W. Williston, Theodore Dru Allison Cockerell, Ephraim Porter Felt, Elmer Darwin Ball, Alexander Dyer MacGillivray.

Mr. Viereck moved to ask the committee on nomenclature to define what constitutes a species and variety, taking into consideration what the ornithologists have done, and that they bring the same up before the Commission on Nomenclature of the International Congress of Zoology one year before the next meeting of that congress.

Adjournment.

At 8 p.m., in the assembly room of McCoy Hall, the annual public address was given before the society by Dr. E. B. Poulton, Hope professor of zoology in the University of Oxford, on "Mimicry in the Butterflies of North America." The speaker was introduced by Vice-president Smith. A large and appreciative audience was in attendance. The address was illustrated by many beautiful colored slides.

J. CHESTER BRADLEY,
Secretary-Treasurer

RESOLUTIONS ON THE DEATH OF DR. WM. H. ASHMEAD

William Harris Ashmead, naturalist, honorary fellow of this society, died on October 17, 1908. We, his colleagues, would hereby give expression to our sorrow in the loss of a leader and a friend—one who gave himself unsparingly to the advancement of the science we cherish, who made himself by his zeal and industry one of the foremost students of the Hymenoptera in the world, and who furthered our progress by his numerous and valuable papers and by the prompt and generous aid he lent to every student who asked his expert knowledge and assistance. We gratefully acknowledge our debt to him, and we desire to place on record this testimonial of our esteem for him as a man, our pride in his successful career, our high regard for his scientific work, and our

sincere sense of irreparable loss at his passing away.

J. H. COMSTOCK,
J. G. NEEDHAM,
J. C. BRADLEY;
Committee

RESOLUTIONS ON THE DEATH OF DR. JAMES FLETCHER

WHEREAS, By the untimely removal of Dr. James Fletcher, the Entomological Society of America has lost—the first by death—one of its original fellows, and former vice-president, who presided at the Chicago meeting one year ago; and

WHEREAS, Dr. Fletcher, by reason of his nobility of character, kindness of heart and zeal, tempered by good judgment, was known and beloved among scientific men not only throughout the whole of the United States and the Dominion of Canada, but also abroad, as a careful, conscientious, scientific worker, a true Christian and a thorough gentleman; and

WHEREAS, His death, almost in the prime of life, is a serious loss to the applied science of entomology as well as of botany in America; therefore, be it

Resolved, That by and through these resolutions the members of this society express their grief over this loss, to two nations, of this truly fine, good man and colleague; and be it further

Resolved, That a page of the *Annals* of this society be set aside for the purpose of placing these resolutions on record and that the secretary be instructed to send a copy thereof to the bereaved family.

F. M. WEBSTER
F. H. CHITTENDEN
C. L. MABLATT

REPORT OF THE COMMITTEE ON NOMENCLATURE

Your committee desires to report that since its appointment, four matters have been presented for its consideration. Of these, one was the consideration of a particular case and was soon settled. The second is still under consideration; the third it has not, as yet, been able to take up, and the conclusions which the committee have reached upon the fourth case are herewith presented.

The nomenclature of gall insects was referred to the committee as the result of a paper by Dr. E. P. Felt presented at the last meeting. The committee is not unanimous on all points, but considers it desirable to present the following:

Report on the Nomenclature of Gall Insects.

In the literature relating to galls and gall in-

sects, there are found several different kinds of description, accompanied by names.

1. Those relating to the galls only, with names intended to apply to the galls, not to their inhabitants.

2. Those relating to the galls only, but with specific names referred to particular insect genera, and intended to apply to the gall insects themselves, these being known at the time only from their work.

3. Those relating to the galls and the contained larvæ, with names proposed to be applied to the insects.

4. Those relating to the galls and the adult insects bred therefrom, and sometimes also to the larvæ, with names proposed for the insects in the usual manner.

5. Those relating to the adult insects, the galls being unknown, with names as usual.

I. It is agreed that in cases falling under 1, the names proposed do not enter zoological nomenclature. It is also obvious that in cases 4 and 5, the names are correctly proposed, and available for use if otherwise in accordance with the international rules.

II. It is the opinion of the committee that specific names based on larvæ (case 3) are available, and may be used.

III. With regard to the description of the gall, it is recognized that it forms a valuable part of the diagnosis of any gall insect, and that without it the recognition of the species may be difficult or practically impossible, especially when the description is not very detailed or precise. The committee is willing to accept a name based on the description of an adult or larva plus gall, even though the name would not be recognizable or of certain application were the account of the gall excluded from consideration.

IV. With regard to names applied as in case 2, intended to refer to the then unknown makers of known galls, it is the sense of the committee that, whenever possible, these names should be adopted.

V. The committee is not wholly in agreement as to whether it is obligatory to maintain names (if otherwise valid) proposed as in case 2; or whether, when they are maintained, the original author and date should be cited, or the author and date of the publication in which the insect itself is first described. The majority of the committee, however, is against the obligatory recognition of names accompanied by descriptions of galls only, and holds that when these are adopted, they properly enter nomenclature at the time of the description of the insect itself.

VI. The committee agrees, that whatever may be the ultimate ruling on the last point, there are many practical difficulties in the way of recognizing names proposed as in case 2, so that even were such names held to be available, many of them would have to be rejected as of uncertain application. It is perfectly clear that no rules will absolve an author from using his critical judgment in the several cases that come before him; and after the rules have declared a name available from their standpoint, it may be a long way to availability from the standpoint of practical identification.

The committee is greatly indebted to Dr. C. W. Stiles, the secretary of the International Commission on Zoological Nomenclature, for a full and luminous discussion of the matters in dispute.

H. T. FERNALD
T. D. A. COCKERELL
E. P. FELT

SOCIETIES AND ACADEMIES

THE MICHIGAN ACADEMY OF SCIENCE

THE 15th annual meeting of the academy was held at Ann Arbor, Mich., March 31 and April 1 and 2. The meeting was made the occasion of a Darwin Centenary Celebration, and the Research Club of the University of Michigan and the Michigan Schoolmasters' Club cooperated with the academy in furnishing special programs. The papers presented were as follows:

Program of the Darwin Celebration

Darwin Program of the Academy of Science.

Address of the president: "The Beginnings of Life from the View-point of a Bacteriologist," Dr. Charles E. Marshall.

"Theories of Animal Coloration, especially Warning Coloration," Professor Jacob Reighard.

"A Contribution to the Theory of Orthogenesis," Dr. Alexander Ruthven.

"American Paleontology and Neo-Lamarckism," Professor E. C. Case.

"The Mutation Theory from the Botanical View-point," Dr. Henri de Leng Hus.

The above papers were, for the most part, devoted to a discussion of the methods of evolution, from the standpoint of the original work of the speakers.

Public address under the auspices of the Research Club of the University of Michigan: "Darwinism and Paleontology," Professor W. B. Scott, Princeton University. In this lecture Professor Scott reviewed the evidence of evolution furnished

by paleontology, and discussed the character of the evidence, using as illustrations the horse, camel, rhinoceros and other mammalian series.

Joint Session of the Science Teachers Section of the Academy and the Biological Section of the Schoolmasters' Club, S. D. Magers, chairman.

The Effect of the Darwin Doctrines:

"On Biology," Professor C. B. Davenport.

"On Psychology," Professor N. A. Harvey.

"On Education," President E. G. Lancaster.

"On Religion," Rev. Carl S. Patton.

As indicated by the titles, the papers presented at this meeting were concerned with the influence of the Darwinian theories upon the different fields of thought represented by the speakers.

Regular Program

Section of Agriculture, A. J. Patten, vice-president. (Held at the Michigan Agricultural College, April 14.)

"Some Reminiscences of the Attitude of Harvard Professors toward Darwin's Work," W. J. Beal.

"Darwin's Influence on Plant Breeding," H. J. Eustace.

"Darwin's Influence on Animal Breeding," A. C. Anderson.

"Further Experimental Work on the Interaction of Plant Roots," J. B. Dandeno.

"Advanced Methods in Milk Analysis," W. E. Robison.

"A Discussion of the Value of Raw Rock Phosphate for Fertilizing Purposes," A. J. Patten.

Section of Botany, Wm. E. Praeger, vice-president.

"Osmotic Theories, with Special Reference to van't Hoff's Law," J. B. Dandeno.

"Investigation on Bordeaux Mixture," J. B. Dandeno.

"The Rapid Extension of Weeds in Michigan," W. J. Beal.

"Origin of the Flora of Local Peat Bogs," Geo. P. Burns.

"The Effect of Longitudinal Compression upon the Production of Mechanical Tissue in Stems," L. H. Pennington.

"The Plasticity of Some of the Compositæ around Ann Arbor," S. Alexander.

"The Phytogeographical Relations of the Mount Ktaadn Flora," L. H. Harvey.

"Notes on Plant Pathology," J. B. Pollock.

"The Carbon Nutrition of a Fungus," Rose M. Taylor and J. B. Pollock.

"The Culture of Fern *Prothallia*," Elizabeth D. Wulst.

"Unreported Michigan Fungi for 1908," C. H. Kauffman.

"Methods of Sterilizing Seeds," R. de Zeeuw.

"Growth of Water Cultures in Various Solutions," N. W. Scherer.

"Variations in Leaves and Flowers," Henri de Leng Hua.

"Variations in the Dimensions of the Tracheids of *Picea excelsa*," S. M. Hamilton and W. H. Ramson.

Section of Geology and Geography, Wm. H. Hobbs, vice-president.

"The Comparison of the Loess Deposits of Europe and America," Frank Leverett.

"The Story of Niagara told in Photographs," Frank B. Taylor.

"An Aegerite-Oligoclase Aplite from the Lake Superior Region," Alfred C. Lane.

"The Differentiation toward the Most Fusible Mineral (Augite) in Non-hydrous Magmas," Alfred C. Lane.

"Occurrence of Sulphur in Sicily," W. F. Hunt.

"The Physiography of an Ancient Delta Region in Texas," E. C. Case.

"Some New Occurrences of Iodyrite," C. W. Cook.

"The Use of Crystallography in the Identification of Commercial Chemical Compounds," E. H. Kraus.

"The Iron Ranges of the Nipigon Region, Ontario," O. Bowles.

"The Iron Ores of Spring Valley, Wisconsin," R. C. Allen.

"New Apparatus for Instruction in Geology," Wm. H. Hobbs.

"The Raw Materials for Portland Cement in Alabama, together with Analyses," W. F. Cooper and Delos Fall.

"The Flint Water Supply," Alfred C. Lane and F. Harlan Bretz.

"Stadia of the Wisconsin Glaciation in North America," Frank Leverett.

Section of Sanitary Science, E. C. L. Miller, vice-president.

"Examination of a Commercial Ferment," W. E. Forsythe.

"The Standardization of Contact Insecticides," H. C. Hamilton.

"The History of the Sausage," Floyd W. Robison.

"The Organization of the Anti-tuberculosis Work," V. C. Vaughan, Sr.

"Situs Viscerum Transversus," Hugo A. Freund.

"Concerning So-called Agglutinoids," E. C. L. Miller.

"Staining of Sections by the Romanowsky Method," F. J. McJunkin.

"A Demonstration of the Effect of Alcohol on Gastric Digestion," S. D. Magers.

"Negri Bodies as a Diagnostic Factor in Rabies," Jas. G. Cumming.

"The Undetected Cases of Diphtheritic Infection of the Nose," Preston M. Hickey.

"Human Myositis," A. W. Blain.

"The Wassermann Reaction," Jas. G. Cumming.

"Trypanosome Infection through Mucous Membranes," W. A. Perkins.

"Diagnosis Leishmania Infantum by Cultural Methods," F. G. Novy and P. A. Schule.

"Leishmaniasis," F. G. Novy.

Section of Zoology, Dana B. Casteel, vice-president.

"Notes on Michigan Reptiles and Amphibians," A. G. Ruthven.

"Notes on the Crayfish of Michigan," A. S. Pearse.

"The Early Development of Neurofibrillae in *Rana pipiens* and *Ambystoma punctatum*," Hansford MacCurdy.

"Amitosis in the Nervous Tissues of Cryptobranchus," Q. O. Gilbert.

"On the Way in which Nematocysts Function," O. C. Glaser.

"Effects of Centrifugal Force upon the Embryonic Development of Some Chrysomelid Beetles," R. W. Hegner.

"The Germ Cell Determinants in Beetles," R. W. Hegner.

"Some Light Responses in the Jelly-fish, *Goniomemus*," Louis Murbach.

"Reaction of Amphibians to Light," A. S. Pearse.

"Method of Preserving Material for Vertebrate Dissection," J. J. Myers.

"Effects of Pressure upon the Embryonic Development of Some Chrysomelid Beetles," R. W. Hegner.

"The Distribution of the *Unionidae* of Alabama," Bryant Walker.

"Notes on a Double Snail (*Campeloma* —)," Hansford MacCurdy.

"Notes on the Skeleton of *Chamaeleon oristatus* Stutchb.," E. C. Case.

"Locality Memory in the Woodchuck," Jacob Reighard.

"Key to Michigan Gasteropoda," H. B. Baker.

"Pearl Organs: A Secondary Sexual Character not Easily Explained through Use," N. H. Stewart.

MR. intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

THE beautiful new building which you to-day dedicate calls to my mind in contrast a plain old building at my own alma mater, in which my college work was done. The four walls of that building were as barren of architectural adornment as the cotton mills in the near-by village. And so the building had been known to many generations of students as "The Mill."

But in our minds our college building was a grist mill and not a spinning or weaving mill. Our college was not a place for spinning yarns, but for grinding away at our studies. Grinds, on each other or on our instructors, served to lighten and brighten our tasks. We considered ourselves choice wheat, which the old mill was to turn into the finest flour.

Realizing the associations which cluster in my mind around that old building, you will understand that I intend no disrespect if I liken your beautiful new building to a mill. A new mill, added to a large and prosperous manufacturing plant. A new mill to turn out a new product.

A new product, did I say? No, not a new product, but a staple article. There was a time, it is true, within the memory of men still young, when the engineering graduate was a novelty in the market—a novelty which sometimes found eager purchasers but which at other times literally went begging.

That era long ago passed away. Training men for the engineering profession in colleges is no longer an experiment. The engineering graduate is a staple product.

But even staple products are sometimes a

drug in the market. No man builds a mill to produce even such staples as flour or cotton cloth, without carefully examining market conditions. It is fitting, therefore, that we survey the market conditions for engineers. How stand the relations of demand and supply? What sort of engineers are most needed to-day? What grade of flour will you set your mill to grind?

Perhaps I can best picture to you market conditions in the engineering profession if I draw a parallel between the engineer and one of his favorite materials—Portland cement.

A quarter of a century ago, Portland cement was an expensive and little used article—just like the engineer of a somewhat earlier period. The valuable qualities and many uses of Portland cement were little appreciated when it was first introduced. The pioneer engineers suffered in like manner. To-day fifty huge mills are producing Portland cement where there was one a generation ago. So where there were four small struggling schools of engineering in the United States in 1850, there are to-day more than fifty times that number, and many of these schools number their students by hundreds and even by thousands.

Manifestly these huge mills for making Portland cement would not have been erected if the public had not found a use for their product. So also the engineering schools could not have multiplied in number and grown in size as they have done if the public had not found the engineering graduate a useful and valuable member of society. But I am bound to say to you that enterprise in the erection of Portland cement mills has at times outstripped demand, and as a result the cement market has been overstocked. The market for engineers follows quite closely the market for cement, and during the past two years

there have been many idle cement mills and idle engineers.

With both the cement mills and the engineers it has been a case of competition, and survival—if not of the fittest, then of those best able to survive. Undoubtedly the increase in cement mills and in engineering schools has had the effect in each case of lowering the price of the product. But it is also true that this low price combined with excellent quality has enormously increased the demand, both the demand for cement and the demand for engineers.

Is the engineering profession overcrowded? Are its members underpaid? If you submit these questions to a jury of engineers, you will, I am sure, receive an affirmative verdict. But I suspect you would have the same sort of answer if you inquired of lawyers concerning the legal profession or of physicians as to the practise of medicine.

It is a fact, nevertheless, that certain changes in our educational system during the past half century have operated to swell the ranks of the engineering profession above that of other professions, and by the competition thus set up have reduced the compensation of engineers.

Half a century ago college education in the United States meant one thing only—the old-time standard course of studies in the classical languages and mathematics, with a smattering of elementary science and theology. With the rapid progress of science and the industrial arts there came about a powerful reaction against this ancient scholastic drill that had so long passed under the name of a liberal education. The demand arose that the college should teach something practical, something that would make the student better fit for his life-work. The answer to this demand on the part of the colleges was the introduction of a great variety of schools and special courses of study. Of all these schools, the

most popular and the most successful unquestionably have been the schools of engineering.

You will hear men blaming the engineering schools for overcrowding the profession. I do not think we can accept that criticism offhand. I grant you it is true that many more men have been graduated from our engineering schools in the past twenty years than can find employment in engineering work; but would it be well for the profession or for the country to have it otherwise? Must we not frankly recognize that of the men who graduate from our engineering schools every year, a very considerable percentage are not fitted by natural ability to become successful engineers?

I have great sympathy for the many individual cases of hardship that result from the overcrowding of the profession. I freely subscribe to the statement that the engineering profession as a whole is not paid in proportion to the responsibility it carries and the useful service that it renders to the community; and yet I can not believe it for the benefit of engineers or of the public to have the paths into the engineering profession made too easy or the rewards for the lower grades of engineering work too great. The older men in the profession can recall times when there were not enough engineers to meet the demand, when any man who knew how to handle a transit could command a good salary as an engineer. Some of the recruits brought in at such times have been an injury to the profession and to the public. An injury to the profession because the work of incompetent men in any profession injures its reputation and limits its chances for profitable employment. An injury to the public because the public has to stand the loss and the disaster that result from engineering incompetence.

It is not, then, a conclusive argument against increase in engineering schools that the profession is overcrowded. I yield to no man in honoring our profession. The best efforts of my life have been devoted to its advancement; but when the question is squarely put whether there are too many engineers, I am obliged to answer, there are none too many good engineers even though there be a surplus of poor ones. If engineers are underpaid, as I believe they are, it is because the public which employs engineers does not yet appreciate how valuable high-class engineering work is. Somebody has defined the engineer as a man who can do with one dollar what any fool can do with two. When all members of the profession appreciate and act on that definition, the public can well afford to pay princely salaries to its engineers. How many millions of dollars do you suppose might be saved annually in the United States if high-class engineering were substituted for mediocre engineering? Let me give you an example in just one single industry: steam power plants for generating electric current. One of the most prominent engineering firms in this country recently authorized the following statement: If good engineering were used in the design and operation of electric stations in the United States, a saving might easily be made of one fourth cent per horsepower hour, and that would have amounted last year to no less than \$37,000,000.

I deprecate that competition in the engineering profession which lowers the pay of engineers. Competition in engineering ought not to be in rate of pay but in quality of service. A few days ago I received a letter from an official board asking what would be a proper salary to pay an engineer for taking charge of a piece of hydraulic construction involving an expenditure of a million dollars. I replied

that the salary they should pay ought to depend on the sort of man they secured. If they engaged a man of exceptional ability he would probably save them so much in the cost of the work that they could well afford to pay him twice or thrice what they would pay an ordinary engineer.

I am not here to indict my own profession. Far from it. But every member of it who has reached mature years, held large responsibilities and come in contact with engineers of all sorts in actual work, will confess that a very large amount of work is done poorly that ought to be done well. That many, many millions of dollars are wasted that might be saved by better design, better supervision, better execution. Engineers, let us confess, are not exempt from the frailties of humanity. Some of us are lazy, and will take the easy course and let things run on in the rut of routine rather than make the effort to prepare new designs to meet changed conditions. Some of us are arrant cowards, and rather than run any risks we will spend money like water—so long as it is not our own money. I have seen engineers of this type take credit to themselves for their conservatism, and prate in official reports about the high-class construction they had secured, when the fact was that they had spent thousands where hundreds would have satisfied every requirement.

I am perfectly well aware that there are men who defend that type of engineering. They claim that an engineer's business is only to look after accuracy, strength, permanence and safety in construction; to use only the best materials and accept nothing but the highest class of work. It is engineers of this type who are responsible for the idea, still too commonly held, that to put an engineer in charge of work means a great increase in its cost. If we had less such engineering, there would be a greater demand for engineers.

I am able to give you a personal illustration of the difference between the two types of engineering. Within forty-eight hours I have talked with men in Washington who know of the work your director has done there in a great government department of engineering work. He had the good sense to see that this work was only a means to an end, and that accuracy and hair-splitting refinement were only valuable where they were effective in the final result. He solved the problem, "What is worth while," and his solution has saved to the government tens of thousands and probably hundreds of thousands of dollars.

I want to see more engineers who are able to wisely solve this problem, "What is worth while," in a hundred lines of engineering work.

How many hundreds of millions of dollars do you suppose are expended annually in the United States in the promotion of foolish and absurd inventions or enterprises wrongly planned? It has long been a theory of mine that people ought to be saved from losing their money in such schemes by seeking the advice of engineers. But I have found that before my theory can be put into practise, we must have engineers who are wise enough and broad enough to give reliable advice on such matters. And the public must learn to discriminate between the engineers who know and those who only think they know.

I think it well to set forth these facts here for the encouragement of those who may be looking forward to the profession and who may have the feeling that engineering work has already reached such a stage of perfection that there is no room in it for further advancement or greater achievements. There is room and need today for better engineers and for a higher grade of engineering work.

And so your mill, although it is to grind out a staple product, is not designed to

undersell the market. You are not aiming merely to increase the output of engineering graduates. Your president has clearly emphasized in his address that it is not cheap engineers but better engineering that the public needs.

Magnificent work has been done for the engineering profession by our colleges. I believe our American system of training men for the engineering profession is far in advance of that in vogue in any other country. We must recognize, however, that the rapid changes in science and industry and engineering make changes necessary in our engineering schools. Imagine a boy to-day taking the course of study that was required at the Rensselaer Polytechnic Institute sixty years ago, and then going out to do engineering work. A high-school graduate of 1909 would be in many ways better equipped.

Go back only a quarter of a century and you will find that the engineering courses then in vogue would not suit present-day requirements. It is no argument for those courses that men who graduated from them have achieved eminence in the profession. Many men who were denied all educational advantages have become great by sheer ability.

So we face the question, What education shall the engineering college give to its students to-day that shall best fit them to win success in their profession?

I have called your institution a mill which is to turn raw material into a finished product. Well, it is raw, sure enough, but let us remember that the material is alive—and let us hope very much alive. I believe, after all, your college is not a mill, but—begging the pardon of the freshman class—a greenhouse.

Engineering education, like any other education worthy of the name, is a process of growth. To achieve success in your greenhouse culture you must have the

right sort of plants to start with. Unless a boy has natural abilities of the right sort you can not make him into a good engineer.

On the other hand, boys with good natural abilities who can not afford a college training are going out into the working world all the time, beginning at the bottom rung of the ladder in some line of engineering industry, educating themselves in the school of daily experience, aiding that development by study in night schools and correspondence schools and by wide reading and observation.

I want to leave a wide door open into the engineering profession for the men who obtain their education in such a way. I want to deprecate any petty prejudice on the part of college-trained engineers against the engineers who have won success despite their lack of systematic college training. Such prejudice is as unworthy as that with which the so-called "practical" man met the engineering graduates of a quarter century ago.

The engineering colleges to-day must recognize the aids that are now available to the boys outside of the college, in the shape of the correspondence schools, for example. The question is, How shall the boy who spends four years or five years in the college achieve such growth that he can excel in competition the boy who has meanwhile been learning engineering by doing practical work.

For the past twenty years, the engineering colleges of the United States have been trying to answer this question by specializing their instruction in engineering, by multiplying the number of their courses, by trying to make men expert in one particular limited branch of engineering work. Now I am far from denying that there is a large demand and a certain field of usefulness for such special courses; but I believe the consensus of opinion among those best able to judge is that there has been too

much specialization in our engineering instruction. We have to-day in the engineering profession many specialists, but too few men with broad knowledge, broad abilities and a broad outlook.

One common defect in your self-taught engineer is that, however proficient he may be in the one field where he has had experience, he knows little outside that field. It is the lot of most engineers to change their occupation many times in the course of a lifetime. One branch of engineering work falls off and they are obliged to turn to another. It is the advantage of the man with the broad college training that he can do this with facility. The specialist, however, when work in his specialty fails, finds his occupation gone.

Perhaps the error which is most to blame for the specialization in our college courses is the error that the college education in engineering produces an engineer. The engineering graduate when he leaves the college halls is not yet an engineer, and would not be one even if you doubled the length of your course. There are indeed exceptions. An occasional young man of great ability and with a practical bent of mind will get enough out of his college course, supplemented by wide reading and vacation work, to be fit for considerable responsibility at graduation. But such exceptions only prove the rule. The college course in engineering is only laying a foundation on which the finished superstructure is to be erected through accumulated experience in actual work.

Now it may seem to some of you students a little disappointing to spend four or five valuable years and then only succeed in laying the foundation to become an engineer. But I want to assure you that it is in this very matter of foundation that the college-trained engineer has an advantage over his professional brother who "picks up" engineering. With a broad and deep

foundation, there is no limit to the size of your superstructure and no limit to the speed with which you may erect it.

But the boy who starts in at engineering work when he leaves the common school is like one erecting a building and putting the foundation under it as he goes along. The job is not impossible, given patience and perseverance enough, but it takes a lot of both. Progress is slow, and the chances are that the man will be satisfied finally with a modest structure. Besides, foundations put in in this way are never quite as strong, never quite as reliable, as those built in the regular way. Sometimes such foundations fail and down comes the building.

The business of the engineering college, then, is to lay a broad, secure foundation. I am not objecting, mark you, to schools of a different sort. There is room and need for correspondence schools, for night schools, for industrial schools, for schools that may give special instruction in special fields. But if you aim to give an education to young men that will best fit them for high and responsible positions in the engineering world, then you must make your training a broad foundation.

And let me carry the simile one step further. You will find great difficulty in laying a secure foundation in a deep swamp or in fathomless quicksand. It will be a far better foundation if underlaid by rock or hardpan. So if you want to build a good foundation of engineering education, you must have to start with a boy of proper mental and moral and physical make-up. Now how will you restrict your work to such boys? That is, I think, one of the most difficult problems which our American colleges have to solve.

They are trying to solve this problem by raising their entrance requirements. They are trying to solve the other problem, how they may send out only high-class men into

the profession, by increasing the work of the college course. These are probably necessary changes; and yet I want to sound one note of warning:

There is danger, I believe—and I am not alone in this belief—that you may shut out of your engineering courses boys who have natural abilities which fit them for success as engineers and yet are deficient in some branch of study, perhaps mathematics or the languages.

I do not underestimate the value to an engineer of either of these branches; yet I feel that they have been often overestimated in the framing of our engineering courses.

There is danger, if you place your emphasis too much on purely scholastic attainments in your engineering schools, that you may raise up a generation of scholastic engineers, expert in theory but weak in its practical application. The mathematical side of the profession and even the research laboratory have been, if anything, overdone already. We must lay broader foundations than these typify if your graduate is to successfully compete with his rival, educated in the school of hard knocks. A broader training than this is needed if your engineer graduates are to meet the demands of this twentieth century.

Do you say, what are these demands? I want to impress upon you that the country to-day needs engineers of high type as it never has needed them before. Few realize the enormous change that has taken place in the relations between the engineer and the public. Go back less than a century—no longer ago than the lifetime of men still living—and you find the engineer almost unknown. Civilization and industry knew his prototype—the millwright, the builder, the miner; but their art was the art handed down by tradition, crusted over with superstition and error. The applica-

tion of science and the scientific method to industry had barely begun.

Go back half a century and we have the beginnings of engineering: the railway, the steamship, the development of the mine and the waterfall. There were great men among the engineers of those pioneer days. We do well to honor their achievements. Yet the problems of that day, seen in our present light, were simple. The engineer was a necessity in very few industries. His art was not yet so complicated that it could not be mastered by the diligent student with little aid in the way of text-book or teacher.

But the period since the civil war, and particularly the latter half of that period, have seen social, economic and industrial revolutions, such as the world has never before witnessed. Civilization finds itself face to face with a multitude of perplexing problems. And a very large number of these problems are so interwoven with our industrial development that the engineer is needed to aid in their solution.

I have told you that engineers are needed to effectually solve the problem, "What is worth while." Is it worth while to spend two hundred million dollars to build one kind of lock canal at Panama, or three hundred million dollars to build the one we are now completing, or five or six hundred millions to build a sea-level canal? Is it worth while for the government to spend half a billion dollars on waterway improvements? Is it worth while for a state to spend a million or ten millions on good roads? How much ought a city to spend on sewage disposal, on the purification of its water supply, on lighting its streets?

I know engineers who shirk these questions, who say that the engineer should take a humble back seat while the statesman, the lawyer, and—if you please—the ward alderman decide these questions.

I tell you, gentlemen, this is a huge mis-

take. Our statesmen and lawyers and aldermen—even when they are honest and well-meaning—are sadly lacking in knowledge, except it be that little knowledge which is proverbially so dangerous.

For lack of wise engineering leadership the public is being led to-day toward many an unwise and wasteful expenditure. Men are going up and down the land to-day fostering fallacies and errors—errors which will directly affect our national welfare unless good sense and good judgment can be invoked to correct them.

No student of history can fail to be impressed with the importance to a people of able leaders. The prosperity of our own favored nation rests no more certainly on natural resources and on an intelligent and law-abiding people than it rests on wise leadership. The opportunity for leadership is open to the engineer. His technical knowledge is essential to the wise solution of public problems. Can he couple with his technical knowledge those other qualities which are essential if the public is to be safely guided?

And what are some of the qualities? Well, I would name first of all what I may term the judicial spirit. An engineer has no business to be governed by prejudice or partisanship. His sole object ought to be to find where the truth lies. He must constantly make choices in his daily work, and sound judgment in such choices is a first requisite. Of course he must have the knowledge on which to base a judgment; and yet when I am asked to recommend an engineer for large responsibilities, I look first of all for a man of broad mind, one who is able to weigh matters fairly and judge without prejudice. Even though such a man be compelled to rely on others for some part of the technical knowledge required, he is a safer counselor by far than a man of small caliber, though the latter be loaded to the muzzle with facts and theories.

The public has some reason for distrusting the judgment of so-called experts. If your expert has been a man of one idea too long, there is danger that his grasp of broad principles may be deficient and that his judgment may be warped.

Can you develop in your students who go out from this institution those qualities of mind and heart and character which will in later years ripen into sound judgment? If they gain such development from their college training they will gain something much more rare and valuable than knowledge of hydraulics or expertness in the testing laboratory.

Does it seem to you impossible to cultivate in your college course such personal qualities as the judicial spirit? I grant you that a proper mental equipment in the student is essential at the start; but given that, ought not the college years—the formative period of a man's life—to be effective in cultivating just such qualities? Do not our American colleges and universities miss their highest opportunity if they fail to develop in their students a broad outlook, fair-mindedness, keenness to discern error, love of the truth?

I have emphasized the need of engineering leadership. But the essential to leadership is the ability to deal with men. Your engineer may be a master of professional knowledge. He may have even the good judgment necessary for its application; but if he can not meet men face to face and hold his own with them, his professional ability will not win him the highest success.

Every engineer of long experience knows that the ability to write a clear report or a strong letter, to speak forcibly and convincingly, either to one man alone or an audience of hundreds—ability to do things like these is as valuable to an engineer as technical knowledge. Training in writing and in speaking is being emphasized more and more in our engineering courses.

And there are other qualities that make for leadership: tact—the combination of good judgment with good taste in dealing with others; self-confidence without self-conceit; a personality that attracts men, wins their confidence, holds their loyalty. It is qualities such as these that make the leader of men. It is such choice qualities as these that the atmosphere of our universities ought to develop in their students. Was it not with such high ends in view that our universities were founded?

Your splendid new building has higher purposes than a mere mill. You will not rate its success in dollars and cents of annual profit. And I want to protest against the too common standard by which we rate the success of men. You tell me that this graduate holds a \$25,000 position, that another owns a rich copper mine and a third is president of a colossal trust. Have they achieved success? Very likely; but why not apply to them the same standard that we apply to your university?

The true measure of success, alike for the university and for its graduates, is the test of public service.

I know an engineer who has through long years guided the destinies of a great city, saved to its taxpayers untold millions of dollars, fostered its development in a way that will benefit generations yet unborn.

I know an engineer who dared to risk his professional reputation and his life to uncover fraud upon the commonwealth and to punish the guilty.

I know an engineer who has turned a barren desert into fruitful farms, has made possible prosperity and happiness to thousands and tens of thousands.

It is true that the public seldom appreciates the value of such services as these, and those who render such service often receive only meager reward; and yet I tell you that it is achievements like these that best deserve the name of success.

Shall we not then dedicate your new building to the culture of such high ideals? Within its walls may all noble traditions, all honorable standards, be fostered and upheld. May those who go forth from its influences carry with them a rich spirit of loyalty—loyalty to the public welfare, loyalty to their city, their commonwealth, their country. So will they justify those who to-day dedicate this building to public service.

CHARLES WHITING BAKER

THE NEW COLLEGE OF ENGINEERING, AN OPPORTUNITY¹

A GREAT opportunity is before us. Through the generosity of Mrs. G. F. Swift and Mr. Edward F. Swift an excellent building for the new College of Engineering has been erected and its maintenance provided for. The board of trustees has determined to furnish the necessary funds to develop the new college. It will start with all the advantages, and they are many and not easily measured, of being a new department of an old and prosperous university, rather than a new, separate organization. Those persons at Northwestern who have fostered for years the idea that engineering should be taught at this university have had high ideals for the new college which have already helped it. The position of the new College of Engineering, within easy reach of one of the greatest centers of commerce and industry in the world, will furnish its students and professors unusual opportunities to keep in touch with the practising engineer. The new College of Engineering is being started at a time when the methods of engineering education are rapidly changing and developing. This is, therefore, an opportune time for it, if properly guided, to take and

¹ Address delivered at the dedication of the new College of Engineering of Northwestern University by the director-elect.

to hold one of the leading positions in the progress of engineering education. It is much easier for a new organization to develop along new lines than for an old organization to learn new ways.

In order to utilize well this great opportunity it is important that we should have a reasonably well-defined ideal toward which to strive. The ideal should be one from which effective working plans may be developed. To work without an ideal is to invite disaster from the changing currents of general tendencies and of personal opinions, and the strong deep currents of prejudice, or to invite disaster upon the shallows of undirected effort. To choose too high an ideal, one toward which we can not make considerable progress in our approach, is to provide for the formation of working plans which will be ineffective, discouraging to the workers, wasteful of effort and resources.

We might take it as our task to convert the high-school graduates who come to us as freshmen into men who will leave these grounds five or six years later as engineers fully trained and completely equipped mentally for their life work. This ideal can not be even approximately attained. To adopt it would lead to misdirected effort and to wasted opportunities.

Instead, our ideal should be so to train these young men in college that they will be capable of becoming engineers, and will have a tendency to become great engineers. We may hope to make a reasonably close approach to this ideal. We may hope to lay such a foundation of motives, of methods of thought, of principles which have been mastered, and of acquired information, that our graduates may, with accumulated experience and strength acquired by effort, become good engineers ten years after commencement, and in the unusual cases become great engineers within twenty of service.

Having this as our ideal, some of the general features of our working plans will follow naturally.

As it is not our purpose to attempt to graduate fully equipped engineers, we need not attempt to give each student special training in the particular narrow branch of engineering which he expects to follow. We need not attempt to teach the future railway engineer all the minutiae of that occupation. We need not try to give to the future sanitary engineer all the specific information needed in his chosen line. As our purpose is to equip the graduate for unlimited growth as an engineer, rather than for the greatest immediate usefulness, it is obvious that we should put the emphasis in our teaching strongly upon the fundamentals which are the basis of the specialization in engineering, upon mathematics, chemistry, physics and mechanics.

So, too, in selecting the purely engineering courses which are to be given, each should be examined to ascertain the extent to which it is fundamental, the extent to which it deals with principles of broad application, rather than with principles applicable in a narrow field only, or with mere engineering information. A selection among engineering courses must be made, for it would probably require at least eight years in college for any one student to take all of the different courses now offered to undergraduates in colleges of engineering.

In teaching the broad principles which underlie engineering, in passing to the student that well-organized knowledge contained in the text-books and treatises on engineering which has aptly been called concentrated experience, the college has great advantages over the school of experience. On the other hand, skill, special knowledge and that familiarity with details which is a part, but not all, of experience, may clearly be best obtained outside the college, in the practise of engineering.

These considerations indicate approximately how to make the difficult decisions as to the amount of shop work, laboratory work and drafting which should be put into our curriculum. These courses serve in part one purpose, to illustrate principles, to make them concrete and thereby both to strengthen the grasp of the student upon the principles and to increase his interest in them. These courses, especially if made extensive, also serve another purpose, namely, to develop some skill and judgment in the manipulation of instruments, tools and apparatus. In accordance with our ideal, we should endeavor to stop when the first purpose has been accomplished. To endeavor to accomplish the second purpose also by more shop work, laboratory work and drafting during the college years will necessarily crowd out other courses in lines in which teaching may be done much more effectively in college than out of it.

The student should, however, be encouraged to engage in practical work connected with engineering, during his summer vacations. He may gain from this, in somewhat the same manner as from his first experiences after graduation.

In the statement of our ideal we have acknowledged that the embryo engineer has much to learn after he leaves college and before he becomes a full-fledged engineer. It follows, therefore, that it will be a mistake to keep him too long in college, just as truly as it will be a mistake to turn him out too soon, with too little training. With each year added to his life, the man tends to become less quick to learn new ways, less keen to profit by new experiences. We should not delay unnecessarily the date on which our graduate begins his work in the world. While he is in college he is surrounded by men who are endeavoring to teach him. He has put before him organized knowledge, carefully arranged and carefully presented. As soon as he steps

out of college, or at least as soon as he rises above the lowest rank in his profession, the knowledge which it is most important for him to acquire is that which lies outside the field of well-organized knowledge. It comes to him in chaotic fashion. His fellow workers and his official superiors have but little interest in helping him to learn, and have still less activity in that line. With each additional year the young man stays in college, it becomes more difficult for him to adjust himself to this radical change in conditions when he goes out.

For the present, we have adopted a five-year course for engineers. Past experience in colleges of engineering shows that a four years' course is too short. The considerations just touched upon should lead us to examine with care any other considerations which seem to indicate that the course should be extended to six years.

The adopted five-year course for engineers is so arranged and provides for such liberal training that at the end of the first four years the successful student will have fulfilled all the requirements for, and will receive, the degree of bachelor of science from the College of Liberal Arts. An engineering degree will be granted at the end of the fifth year.

We have adopted as our ideal the proposition that we are to train engineers for the greatest average effectiveness in the first year after graduation. We should, therefore, avoid sending out our graduates handicapped by ignorance of men. The young engineer, or the old unsuccessful engineer, so long as he remains in such a minor position that he has no official subordinates and never needs to take the initiative, is but little handicapped by ignorance of men. But as soon as he begins to rise, and in proportion to the extent to which he must necessarily depend on those below him for details and for loyalty, on those around him for cooperation, and must

be trusted by those above, his progress is dependent upon knowledge of men. Cases are not infrequent in the engineering world in which the upward progress of an engineer is absolutely stopped by his clumsiness in dealing with men, even though he has great skill in dealing with materials and forces. It is our duty to teach our future engineers not only about forces and materials, but also about man and his ways, to bring it before them with emphasis that their future success in utilizing their engineering knowledge and skill depends upon their ability to work with men, among men and through men.

In the College of Engineering we may expect certain difficult problems to be ever present, intertwined with a multitude of other problems. The success of the college depends largely upon our success in solving these problems which are easily overlooked and neglected because of their familiarity. I intend to suggest but three examples.

Language is one of the important tools of an engineer. He must ordinarily do his work through others. He must have the power to convince. He must have the ability to use English accurately and effectively or be handicapped even in his strictly engineering work. One who acquires the ability to speak and write accurately and well, usually secures with it the power to think accurately. How can we best help the student in his college days to acquire the ability to speak and write well? This is a problem common to all colleges and to all universities. To one who deals much with recent graduates, it is discouragingly evident that but mediocre success has been attained in universities in solving this difficult problem.

It is a comparatively easy matter to lead a student along a given line of thought, but how can the student be trained to think for himself? That is one of the exceedingly difficult problems which confront us in the

College of Engineering in common with all parts of the university.

We should aim, in the College of Engineering, to give our students a broad training, yet we desire to give them thorough training along certain lines. How is the broadening to be secured? Is it to be gained from certain courses intended for that especial purpose, or is it to be secured by the manner of teaching each course, even technical courses? This, again, is a problem common to nearly all, if not all, parts of the university.

The real success of the College of Engineering is dependent upon the solution of ever-present problems of which these are but examples. Because of the existence of numerous problems of this character which are common to the whole university, the College of Engineering gains strength from being a part of Northwestern University, rather than a separate institution. Because the engineer has a peculiar point of view, and the courses in engineering have some special advantages in connection with certain of these universal problems, the College of Engineering may hope in time to contribute a share toward the solution of these problems in this university.

Let us adopt as the motto of the College of Engineering the words, "Culture for usefulness." Let us put the emphasis strongly on the last two words. The first word alone may lead one astray, but the three together are a sure guide. The attempt to gain culture for the purpose of increasing one's usefulness in the world is essentially unselfish. In setting this motto before our students and in thus suggesting that they are to seek culture, not primarily for themselves, but in order to increase their usefulness in the world, usefulness of the broadest kind in the great united struggle of man for progress, we shall be setting before them an ideal which includes all others, an ideal which urges one

to the broadest attainable culture, in college and afterwards, an ideal which is inspiring and invigorating to any one who realizes its meaning.

We are here to-day to dedicate a building to engineering education. In a deeper and better sense, we are here to dedicate ourselves to the highest and best use of the great opportunity which the building represents, an opportunity to give an uplift to the ideals and to increase the usefulness of thousands of young men who are to enter their life work through that building, an opportunity to help in raising the standard of engineering education, an opportunity to help in making American universities of greatest real service to American people.

JOHN F. HAYFORD

NORTHWESTERN UNIVERSITY

COMPARATIVE ENROLMENT OF STUDENTS OF ENGINEERING

It is generally supposed that the attendance on the engineering schools of our country continues to show the rapid gains that have marked their development during the past ten or fifteen years, and while at the majority of the institutions the enrolment of to-day compared with that of say five years ago would exhibit a healthy increase, an analysis of the accompanying table proves that a reaction is apparently beginning to set in, at least at a number of the institutions. It will be seen from the table that the present total attendance of engineering students at twenty-four representative institutions shows an increase over last year of only one hundred and ninety-one students, or one of 1.15 per cent. The figures given include students of engineering, mining and metallurgy, and chemistry, but are exclusive of students of architecture (with one or two exceptions), agriculture, forestry, biology, etc. It should be noted that a number of institutions (for example, the Massachusetts Institute of Technology) have one or more of these last mentioned courses, and that the figures in the table do not, therefore, represent in every case

the total registration of the school. In some instances (for example, Michigan) graduate students are included, in others (for example, Columbia) they are not; most of the institutions submitted the spring registration, but in a few cases the fall figures are given, and there may be several other minor differences, yet in spite of these discrepancies, the table as given will convey a sufficiently accurate idea of the most recent changes in engineering attendance. Owing to the regulation requiring a baccalaureate degree for admission to the school of applied science, which has recently become operative at Harvard, the figures of this institution have been omitted, since a comparison would be somewhat misleading. Thirteen of the institutions exhibit a gain in attendance over last year, while eleven show a loss. It is interesting to note that of the independent schools six show losses in attendance as compared with last year, whereas only five of the schools connected with universities have experienced a decrease in enrolment since 1907-8, while eight schools connected with universities and five independent schools show gains.

RUDOLF TOMBO, JR.

SCIENTIFIC NOTES AND NEWS

By unanimous vote of its council the American Psychological Association will hold its next meeting in Boston in affiliation with the American Association for the Advancement of Science.

At the colloquium of the American Mathematical Society, to be held at Princeton University, September 15-17, courses of lectures will be delivered by Professor G. A. Bliss, on "Fundamental Existence Theorems," and Professor Edward Kasner on "Geometric Aspects of Dynamics." Professor J. H. Jeans having resigned his position at Princeton, the course of lectures announced to be given by him has been cancelled.

In connection with the Darwin centenary, at Cambridge, it is proposed to confer the degree of doctor of science upon E. van Beneden, professor of zoology in the University of Liège; Robert Chodat, professor of botany in the University of Geneva; Francis Darwin, F.R.S., of Christ's College; Karl F. von Goebel, professor of botany in the University of Munich; L. von Graff, professor of zoology in the University of Gratz; H. Höffding, professor of philosophy in the University of Copenhagen; J. Loeb, professor of physiology in the University of California; E. Perrier, director of the Natural History Museum, Paris; G. A. Schwalbe, professor of anatomy in the University of Strassburg; H. von Vöchting, professor of botany in the University of Tübingen; H. de Vries, professor of botany in the University of Amsterdam; C. D. Walcott, secretary of the Smithsonian Institution; E. B. Wilson, professor of zoology in Columbia University, and O. R. Zeiller, professor of paleobotany in the École Nationale Supérieure des Mines, Paris.

MR. PHILLIP FOX, of the Yerkes Observatory, has been nominated by the Chicago Astronomical Society, to be director of the Dearborn Observatory and professor of astronomy in Northwestern University in succession to the late Professor Hough.

PROFESSOR C. H. EIGENMANN, professor of zoology and dean of the Graduate School of the Indiana State University, has been ap-

pointed curator of ichthyology at the Carnegie Museum, Pittsburgh, with the understanding that his appointment will not interfere with his duties in connection with the Indiana State University. Professor Eigenmann will work up the large collections belonging to the museum at his home in Indiana, and will during the summer months devote a portion of his vacation to directing others in arranging the collections systematically.

DR. VICTOR STERKI, of New Philadelphia, Ohio, known for his work on the North American *Pupidae* and allied families, has been appointed an assistant in conchology at the Carnegie Museum. Dr. Sterki's collection became the property of the museum some years ago.

MR. E. DANA DURAND, deputy commissioner of corporations, has been appointed director of the Census to succeed Mr. S. N. D. North.

PROFESSOR SIMON NEWCOMB has left the Johns Hopkins Hospital and returned to his home in Washington.

PROFESSOR DÜNKELBERG, formerly director of the Agricultural Academy at Poppelsdorf, has celebrated his ninetieth birthday.

In addition to the list of delegates to the Darwin celebration of Cambridge University, printed in a recent issue of SCIENCE, the National Academy of Sciences will be represented by Dr. George E. Hale, of the Mount Wilson Solar Observatory, and the Massachusetts Institute of Technology by Professor William T. Sedgwick.

MR. S. F. EMMONS, of the U. S. Geological Survey, has been appointed a delegate to represent the National Academy of Sciences at the five hundredth anniversary of the foundation of Leipzig University, which will be celebrated on July 28 to 30, 1909.

MR. W. BATESON, F.R.S., will give the Huxley lecture at Birmingham this year.

MR. C. G. ABBOT, director of the Smithsonian Astrophysical Observatory, has left Washington for Mt. Wilson, California, to continue there during the summer and fall observations in progress for a number of years as to the intensity of the sun's rays and the effect of any variation in them upon the earth.

There has recently been erected on Mt. Wilson a small permanent observatory especially designed for this purpose. Here Mr. Abbot, with the assistance of Dr. L. R. Ingersoll, of the University of Wisconsin, will study during the next few months. The expedition will also spend some time on the summit of Mt. Whitney, 14,500 feet high, where the Institution plans to erect in July a shelter of stone and steel for the use of scientific investigators engaged in researches of any kind for which high altitudes, dry air and clear skies are desirable.

RALPH S. TARR, of Cornell University, will spend the summer in making a further study of the glaciers of Alaska. He will be accompanied by Professor Lawrence Martin, of the University of Wisconsin.

PROFESSOR OTTO NORDENSKIÖLD and Dr. Hilmar Skoog will this summer conduct explorations in Greenland.

DR. ALEXANDER PETRUNKEVITCH, honorary curator of arachnida in the American Museum of Natural History, will spend July and August collecting arachnida and other forms of insect life in Texas, Mexico and Guatemala.

PROFESSOR J. HORACE FAULL, of the University of Toronto, has been granted leave of absence for the academic year 1909-10. He is continuing his studies on the cytology of the Ascomycetes, particularly of the Laboulbeniaceae at the Laboratories of Cryptogamic Botany, Harvard University.

SUPERINTENDENT GEORGE MCKERROW, of the department of farmers' institutes in the College of Agriculture, University of Wisconsin, has sailed for England to attend the annual meeting of the British National Sheep Breeders' Societies, held in connection with the Royal Stock Show, June 21, at Gloucester, England. Mr. McKerrow, will deliver the annual address on "How We Can Improve the Sheep Industry."

A PORTRAIT of the late Carroll D. Wright, president of Clark College, has been presented to the college, and will be unveiled at the memorial services to be held on July 14. The speakers will include President G. Stanley Hall for the university and Dean Rufus J. Bentley for the college.

DR. G. A. GIBSON, of Edinburgh, has undertaken to edit the medical and scientific papers and articles of the late Sir William Tennant Gairdner, and to preface the volume with a biography.

A MONUMENT in honor of Michel Servetus will be unveiled at Vienna in the department of Isère on August 14. Professor J. C. Hemmeter, of Baltimore, will make one of the addresses.

M. J. IORNS, Ph.D. (Cornell), who has been for several years horticulturist of the Porto Rico Experiment Station at Mayaguez, died of typhoid fever in San Juan on May 17.

DR. CHARLES BURNHAM PORTER, formerly professor of clinical surgery at Harvard Medical School, died on May 21 at the age of sixty-nine years.

DR. WILLIAM WIGHTMAN, of the Public Health and Marine Hospital Service, died at Guayaquil, Ecuador, on May 17, from yellow fever.

MR. GEORGE C. EDSON, of St. Alban's, Vermont, known for his work on the geology of the state, died on May 24.

DR. BINDON BLOOD STONEY, F.R.S., a distinguished Irish engineer, died at Dublin, on May 5, in his eighty-first year.

M. JULES ERNEST NAVILLE, formerly professor of philosophy in the University of Geneva, died on May 27, at the age of ninety-two years.

DR. HEINRICH VON RANKE, professor of diseases of children at the University of Munich and known also for his work on hygiene, agriculture and archeology, has died at the age of seventy-nine years. Professor Johannes Ranke, the eminent anthropologist and physiologist, of the University of Munich, is his brother, and Leopold von Ranke, the historian, was his uncle.

THE deaths are also announced of Dr. Oskar Emil, emeritus professor of physics at Breslau, at the age of seventy-four years; of Dr. Hermann von Stahl, professor of mathematics at Tübingen, at the age of fifty-six years; of Dr. Alfred Partheil, professor of pharmaceutical chemistry of Königsberg, aged forty-eight years, and of Dr. Otto Biermann, pro-

fessor of mathematics at Brünn, at the age of fifty-one years.

THE seventh International Congress of Applied Chemistry opened in London on May 27, with some three thousand members in attendance. At the opening exercises Dr. Harvey W. Wiley, of the U. S. Department of Agriculture, replied for the United States.

THE ninety-second annual meeting of the Société helvétique des sciences naturelles will be held at Lausanne on September 5-8, under the presidency of M. Henri Blanc.

THE annual congress of the Southeastern Union of Scientific Societies will be held at Winchester on June 9-12, under the presidency of Dr. Dukinfield H. Scott, F.R.S.

AT the National Conference on Criminal Law and Criminology held in celebration of the fiftieth anniversary of the Northwestern University School of Law at Chicago from June 7-9, the Honorable Charles S. Deneen, governor of Illinois, has consented to act as temporary chairman. In order to facilitate organization, the committee of organization will nominate (with his consent) for permanent chairman, James Hagerman, Esq., of St. Louis, sometime president of the American Bar Association. The committee will also nominate for temporary chairman of the Section on Treatment (Penal and Remedial) of Offenders, Dr. E. T. Devine, professor of social economy in Columbia University, New York; for temporary chairman of the Section on Organization, Appointment and Training of Officials, Dr. Edward A. Ross, professor of sociology in the University of Wisconsin, Madison, Wisconsin; for temporary chairman of the Section on Criminal Law and Procedure, William E. Mikell, Esq., professor of law in the University of Pennsylvania, Philadelphia.

THE Chicago Chapter of the Sigma Xi Society held its biennial election of officers on May 25, 1909, which resulted as follows: *President*, E. H. Moore; *Vice-president*, R. R. Bensley; *Secretary and Treasurer*, Oscar Riddle; *Corresponding Secretary and Councilor*, Julius Stieglitz. The paper of the evening was presented by Mr. Bailey Willis, U. S.

Geological Survey, upon "China, the Land and the People."

THE Iota Chapter of the Alpha Chi Sigma Chemical Fraternity was installed at Rose Polytechnic Institute on May 22 by Mr. L. S. Palmer, of the University of Missouri; Dr. J. H. Mathews, of the University of Wisconsin, and Mr. O. C. Stanger, of the University of Illinois. The following men constitute the active members of the new chapter: H. J. Bangert, H. Isenberg, R. S. Wilson, J. V. Davidson, R. L. Flood, F. W. Kroemer, Jr., F. Cohen, J. A. Hepp and D. M. Hubbard. Dr. Carl Leo Mees, president of the institute, and Dr. John White, professor of chemistry, were made honorary members. A banquet followed the installation.

THE launching of the Magnetic Survey yacht *Carnegie* will take place on June 12, 1909, 2:30 P.M., at the Tebo Yacht Basin Company, foot of 23d Street, Brooklyn, N. Y. Miss Dorothea Louise Bauer, daughter of Dr. L. A. Bauer, director of the Department of Terrestrial Magnetism, has been chosen by the executive committee of the Carnegie Institution of Washington to perform the christening ceremony.

In order to put a stop to the serious damage done by persons uprooting ferns and wild plants growing in hedgerows and on commons, etc., in the county of Surrey, England, the Surrey County Council has made the following by-law: "No person shall uproot or destroy any ferns or other wild plants growing in any road, lane, roadside waste, wayside bank, or hedge, common, or other public place, in such a manner or in such quantities as to damage or disfigure such road, lane, or other place. Provided that this by-law shall not apply to persons collecting specimens in small quantities for private or scientific use. A person offending against this by-law shall be liable to a penalty not exceeding £5."

UNIVERSITY AND EDUCATIONAL NEWS

MR. W. C. PROCTOR, of Cincinnati, of the class of '88, has offered to give Princeton University \$500,000 for its graduate school on condition that an equal sum be subscribed within a year.

THE legislature of Pennsylvania at its last session appropriated three hundred and twenty-five thousand dollars to the University of Pittsburgh to be expended for new buildings and maintenance.

By the late Dr. F. W. Draper, Harvard University receives an unrestricted bequest which it is believed will amount to \$100,000.

THE Massachusetts legislature has appropriated \$80,000 for the erection of a fireproof building for the departments of zoology and entomology, at the Massachusetts Agricultural College.

THE New York legislature appropriated \$57,000 for the use of the Agricultural School of St. Lawrence University.

THE Tennessee legislature has passed a bill giving 25 per cent. of the state's revenues for education, 7 per cent. being for the university and experiment station.

THE late Mr. James Duncan has bequeathed a portion of his estate, calculated to amount to about \$300,000 for the establishment of a school of industrial art in Dundee, Scotland.

THE new Institute of Physiology at University College, London, will be formally opened on Friday, June 18, by the Hon. R. B. Haldane, secretary of state for war. The funds for the building of the institute were provided by Mr. Ludwig Mond and Dr. Aders Plimmer and by a bequest of the late Mr. Thomas Webb.

DR. SAMUEL AVERY, head of the department of chemistry in the University of Nebraska and acting-president since the resignation of Dr. Andrews, has been elected president of the institution.

DR. ERNEST MERRITT, professor of physics, has been appointed dean of the graduate school of Cornell University.

AT the University of Minnesota, Professor John Zeleny has been appointed head of the department of physics to succeed Dean Frederick S. Jones, who has been called to the deanship of Yale College; Assistant Professor Anthony Zeleny has been appointed professor of physics, and Dr. W. F. Holman, of Worcester Polytechnic Institute, instructor in

physics; and a new instructorship not yet filled has been created. Assistant Professor H. A. Erikson returns to the department after a year's absence at Cambridge, England, and Dr. A. F. Kovarik has obtained a leave of absence for study abroad.

DR. H. H. HORNE, professor of philosophy at Dartmouth College, has been appointed professor of the history of education at the New York University, to succeed the late Professor Gordy.

DR. CHARLES T. BURNETT, of Bowdoin College, has declined a call to the chair of psychology at Amherst College.

MR. C. T. BRUES, of Milwaukee Public Museum, has been appointed instructor in economic entomology at Harvard University.

MISS MABEL BISHOP, fellow in zoology in Smith College, has been appointed instructor in biological science in the Woman's College of Baltimore.

DR. J. B. LEATHES, of London, has been appointed professor of chemical pathology in the faculty of medicine of the University of Toronto.

DISCUSSION AND CORRESPONDENCE

TO THE PHILOSOPHIC ZOOLOGIST

Whether definite variations are by chance useful, or whether they are purposeful are the contrasting views of modern speculation. The philosophic zoologist of to-day has made his choice. He has chosen *undirected* variations as furnishing the materials for natural selection. It gives him a working hypothesis that calls in no unknown agencies; it accords with what he observes in nature; it promises the largest rewards.

The above paragraph is a quotation from the address of my friend and colleague, Professor T. H. Morgan, delivered in the Darwin course at Columbia University, February 26. It is interesting as showing the absolute divorce between the zoological and paleontological observer, a matter to which I have called renewed attention in my Baltimore address recently published in "Fifty Years of Darwinism."

If the word "undirected" implies fortuity, as I presume it does, it is an interesting future possibility that the theory of the building up

of adaptations out of the natural selection of undirected variations, to use my colleague's language, may prove to be a dogma quite as unsupported by facts as the Lamarckian dogma of the inheritance of acquired characters. I long ago pointed out that a very large number of new characters in the hard parts of mammals are adaptive in direction from the beginning; I am very far from saying that *all* new characters are adaptive in direction; I only make this statement as to those characters I have had the opportunity of repeatedly observing.

I now challenge the zoologists to produce a single instance of a series of animals in which adaptive characters are being accumulated through the *selection* of undirected variations, *i. e.*, of variations which are thoroughly mixed up, in which *there is no law evident*. Such a series has never been produced by any one. Of course I bar from this challenge orthogenic changes of character under environmental influences. I refer to the *pure* Darwinian hypothesis. The hypothesis is still as Darwin left it, an ingenious working theory, awaiting either experimental evidence or evidence of any kind. How long this assumption will pass muster as based on observation it is hard to say. We await some paleontological Weismann who will smite it hip and thigh as the zoological Weismann smote Lamarck's assumption.

While the "philosophic zoologist" of to-day has made his choice, the philosophic paleontologist has also made his choice. The latter certainly does not find direction in the old teleologic sense, but quite as certainly he finds no evidence of such fortuity as will justify the use of the word *undirected* as furnishing materials for natural selection. The materials for natural selection are furnished by the *ensemble* of an enormous number of characters, each of which is a unit pursuing its independent history and fluctuating and mutating and moving in direct lines under laws which the philosophic paleontologist has proof of, but totally fails to understand. Consequently he assumes the agnostic position that there is some principle, or principles of direction, or better—to use Professor Morgan's own words

—"unknown agencies," still to be discovered other than the principle of order coming out of fortuity.

HENRY FAIRFIELD OSBORN

NELSON'S LOOSE LEAF ENCYCLOPEDIA.

TO THE EDITOR OF SCIENCE: In February an article was published in Nelson's "Loose Leaf Encyclopedia" upon the Messina-Reggio earthquake, the authorship of which was credited to Mr. Frank A. Perret and myself. In justice to Mr. Perret, however, it should be stated that he had nothing whatever to do with the preparation of the article beyond furnishing the one item pertaining to the height of the "tidal" wave at Messina which is duly credited to him. The insertion of Mr. Perret's name as joint author was done by the publishers of the encyclopedia without my knowledge or consent, but thus far I have been unable to obtain any correction of their error.

SCIENTIFIC BOOKS

General Physics. By HENRY CREW. New York, The Macmillan Co. 1908.

A Text-book of Physics. Edited by A. WILMER DUFF. Philadelphia, P. Blakiston's Son & Co. 1908.

The publication of these two excellent text-books designed for college classes in physics illustrates the general dissatisfaction among college professors of physics with both existing text-books and accepted methods. There are many difficulties inherent in the teaching of physics and there are many points concerning which the best teachers are to a certain degree undecided. As physics is taught at the present time in most American colleges the time devoted to it is one year during each week of which there are three hours of lectures or class work, accompanied by five or six hours of laboratory work. In this time a student is supposed to cover the field of elementary mechanics, properties of matter and physics proper, including heat, light, etc. Within recent years a demand has arisen for text-books which should have more or less refer-

ence to the different classes of students following the course, the point being that students looking forward to engineering ostensibly need a text-book different in character from that best fitted for other students. The difficulties of satisfying these requirements by any one text-book are insuperable. At the very best the author must make certain compromises and must adapt his book to certain actual conditions, and to the classes with which he is most familiar. It is not an easy matter to prepare a text-book in physics which shall satisfy the obvious pedagogical requirements for physics as a subject in general education and at the same time meet the requirements mentioned above. It is not to be expected that all teachers of physics should feel satisfied with all text-books of physics, from the standpoint either of general purpose or of detail, but the two books under review are certainly admirable in many respects, and are sure to have a well-deserved popularity among American colleges.

The author of the present review is not certain as to the object of such an article. It certainly should not be to point out typographical errors, or even to refer to what may seem to him to be misstatements of facts or of theory. On the contrary, perhaps the best result may be secured by noting both the obvious facts concerning the book and the points by which each differs from other well known books.

Professor Crew's book is a beautiful piece of book-making; the paper, type, wood-cuts and binding are all that could be desired. It contains 515 pages, of which 182 are devoted to mechanics and properties of matter, 64 to wave motion and sound, 61 to heat, 115 to magnetism and electricity and about 100 pages, the rest of the book, to light. The balancing of the various subjects, as shown by this subdivision, is admirable. One would expect that this text-book would prove most satisfactory to any college class; the references to the historical development of the science are most interesting and inspiring; the various machines or experimental facts which are given as illustrations of the general theories are well selected and described with enthusiasm;

in fact, the whole book is permeated with a certain charm thoroughly characteristic of all of Professor Crew's own enthusiasm as a teacher and investigator. Another excellent point about the book is the selection of problems. These contain not only useful arithmetical illustrations, but also questions which require the exercise of reasoning as apart from any use of formulae or numbers. It is only in a few places that the author seems to introduce matter which is too far removed from the elementary character of the general book.

The text-book edited by Professor Duff is a compilation of seven sections prepared by different authors as follows: Mechanics, by Professor Duff himself; Heat, by Professor Guthe; Wave Motion and Sound, by Professor Hallock; Light, by Professor E. P. Lewis; Electricity and Magnetism, by Professor Goodspeed; Electromagnetic Induction, by Professor Carman, and Conduction of Electricity through Gases and Radioactivity, by Professor McClung.

In attempting to prepare a book in this manner there are no unavoidable difficulties provided the general editor is one who has certain executive powers, and certainly in this case the publishers are fortunate in having persuaded a man of Professor Duff's ability to assume the task. As is to be expected in such a compilation, there is a certain degree of inequality, but in this particular illustration it is reduced to a minimum. In fact, the work is admirably done from the standpoint of the general editor. The book contains 666 pages and is divided into the seven sections referred to; 177 being devoted to mechanics and properties of matter, 102 to heat, 45 to wave motion and sound, 143 to light, 154 to electricity and magnetism, including electromagnetic induction, 136 to conductivity of gases, etc. At the end of the various sections there are sets of problems which in the majority of cases are admirably selected. The illustrations are clear, but lack the charm of those of Professor Crew's book; the type and paper are satisfactory, although not so good as to demand special attention.

It is not easy to decide as to the class of students for which this book is designed, be-

cause in some ways the treatment is most elementary and in other chapters use is made of the calculus. The field covered is satisfactory on the whole, as is shown by searching in the various chapters for discussions of all the important general phenomena. It would not be difficult to refer to certain sections which might be omitted with profit, but on the whole there is little to criticize in this respect, for the rights of the individual teacher and author must be respected.

The success of any text-book in physics must be decided from its effect upon the mind of the students who use it. If they are taught by means of it to reason correctly, and if they learn a consistent view of the great phenomena of nature, it has accomplished its purpose. A great deal naturally depends upon the teacher, but certainly in the present case the authors of the text-book referred to above have done their full share. J. S. AMES

THE JOHNS HOPKINS UNIVERSITY

A Manual of North American Diptera. By SAMUEL W. WILLISTON. Third edition, illustrated. New Haven, Conn., James T. Hathaway. 1908. Price, \$4.00 postpaid. Pp. 405, duodecimo, cloth.

The much-desired third edition of Dr. Williston's manual was actually published and some copies distributed about August 28, 1908, but on account of the absence of the author on a fossil-hunting expedition in western Texas only a few copies were sent out until about the end of the year. It has, therefore, received but little notice in reviews up to the present time.

The book, like the preceding editions, is designed largely for beginners. It contains an introduction, a treatise on the anatomy of diptera, suggestions as to methods of collecting, preserving and studying the insects, some general remarks on the principles of classification, a synoptic table of the families and a series of chapters on the families. These last-mentioned chapters each include one family, giving in uniform style the following topics: definition of the family, characters of the larvæ, habits of larvæ and adults (often at some length), and table of genera based on

adult characters. In a few cases the larvæ are to some extent subdivided in a separate table. Several of the chapters are written partly or wholly by other entomologists.

The illustrations form a new and conspicuous feature of the work, numbering nearly a thousand. While recent entomological literature has been drawn upon to some extent, a large proportion of the figures are new and drawn by Williston himself, representing an immense amount of labor on his part.

In the preface, after mentioning the successive publications in which he had attempted to outline the classification of North American diptera, the author states that he feels his work in this line completed with the present publication. Perhaps, for this reason, he has allowed himself to express his views and even his feelings to a greater extent than in former editions. Many passages might well be quoted, either as illustrating generalizations derived from thirty years of strenuous scientific work, or to illuminate points of disagreement between the author and certain younger dipterists. A very few selections must suffice.

Giantism in any group of animals is a specialization, and is, in general, an indication of approaching decadence. . . . No strong or dominant group of flies, like the Tachinidæ, Dolichopodidæ, Syrphidæ or Bombyliidæ, has ever had in the past a larger average bodily size than is found among their living representatives.

On the splitting of genera in the mosquitoes:

I fear even Desvoidy's shade would turn pale with envy in the contemplation of some of the proposed genera of the modern culicidologists.

On the "mere collector":

His labors are hardly more important than those of the microtomist who cuts up frogs' eggs and makes pictures of them.

In the matter of wing nomenclature the common system is wisely adhered to, while the Comstock (here called the Comstock-Needham) is illustrated in a page of wings. Unfortunately, the tabular exhibit of homologous terms is imperfect because Comstock's earlier designations are used. The fact that there are already three distinct forms of Comstock nomenclature in existence is an excellent rea-

son, if any were needed, for not introducing even the latest one into the manual.

In the classification of mosquitoes he expresses strong dissent from the process of continually subdividing the great central mass of the genus *Culex*, but naturally is not in a position to elaborate a system, and is therefore obliged to use one that is not much different from that of Dyar and Knab. In Cecidomyiæ, too, he finds too many genera, and adopts a current generic table only under protest. In Dexiidæ and Tachinidæ the tables were prepared by Professor C. F. Adams. Dr. Williston, wishing the criticism of a specialist on this difficult group, and being unable to secure the assistance of Mr. Coquillett, asked Mr. C. H. T. Townsend to prepare notes on the figures. This was unfortunate, as Mr. Townsend's ideas of genera are extremely radical; it naturally happened that his notes only serve to confuse the subject. He, however, seized the opportunity to erect a few new genera on the figures, which was the more out of place and uncalled for since he promised fuller descriptions in a forthcoming paper. Would that he had reserved his adumbrations in their entirety!

A few errors in typography and other mistakes are corrected in a brief appendix. Typographical or any other sort of perfection must not be demanded in a contribution offered as a gift to science after years of strenuous and wholly gratuitous effort. Professor Williston has acquitted himself well, and has given us a work which no one else in the world could have produced, one not approached in any other large order of North American insects. Nay, he has done still more—he has printed it practically at his own expense, and will not be reimbursed until almost the whole edition is sold. Because I happen to know this I wish the entomological public to understand how great their debt really is. And Professor Williston never occupied an entomological position in his life. He has given himself to science, and that is the greatest offering any man can make.

J. M. ALDRICH

Moscow, IDAHO

SCIENTIFIC JOURNALS AND ARTICLES

The contents of *The Journal of Biological Chemistry* (Vol. VI., No. 2, issued May 10, 1909) are as follows: "On the Composition of Dilute Renal Excretions," by A. B. Macallum and C. C. Benson. Large volumes of water were ingested to increase rapidity of flow and decrease concentration of urine in order to diminish the reabsorption of water and salts in the convoluted tubules of the kidney postulated in Ludwig's theory of urine formation. Estimations of potassium and chlorine in very dilute urine revealed neither a proportionality between salt content of blood plasma and of urine nor a uniform ratio of potassium and chlorine excretion. Secretion of water and salts is therefore not a process of filtration, but is truly secretory; the secretory activity varies for each inorganic constituent. "On the Depression of the Freezing Point Due to Dissolved Caseinates," by T. Brailsford Robertson and Theo. C. Burnett. Casein combines with bases to form "neutral" and "basic" salts of definite composition which produce a definite measurable depression of the freezing point. Estimations indicate a molecular weight of "basic" caseinates of 1,400; of "neutral," 2,000. "The Cerebrospinal Fluid in Certain Forms of Insanity, with Special Reference to the Content of Potassium," by Victor C. Myers. Analyses show that changes in the composition of cerebrospinal fluid occur after death. Protein-phosphates, and especially potassium, are increased. The protein content in dementia paralytica is increased during life. "Human Pancreatic Juice," by Harold C. Bradley. Examination of human pancreatic juice showed an average specific gravity of 1010; alkalinity equal to $N/20$ — $N/10$ sodium bicarbonate; no definite relation between diet and enzyme content; no rennin, invertase or lactase; trypsinogen in all specimens, trypsin in 50 per cent. A study was made of the influence of various conditions upon the activity of lipase. "On a Modification of Lunge's Method for the Quantitative Estimation of Urea," by Clarence Quinan. Lunge's method (*Zeitschr. f. angew. Chem.*, 1890, p. 139) of reducing measurements of

gas volume to standard conditions applied to the estimation of urea in urine by the hypobromite method. "The Relation of Different Acids to the Precipitation of Casein and the Solubility of Cheese Curds in Salt Solutions," by J. L. Sammis and E. B. Hart. The amount of $N/10$ acid required to precipitate casein from a lime-water solution varies with the temperature, kind of acid and age of solution. The solubility of cheese curds in salt solution depends upon the kind of salt and the concentration. It is influenced by contact with acids. "An Endeavor to Account for the Transfer of Proteid in Inanition," by Albert Woelfel. An attempt to explain why some tissues waste more than others during inanition by comparison of autolytic and heterolytic digestions. Results negative. "Proceedings of the American Society of Biological Chemists," in session in Baltimore, December 28-31, 1908.

The Museums Journal of Great Britain for March describes "A Method of Mounting Eggs," by Raymond Bennett, in use in the Ipswich Museum; and Mrs. Roessler tells of "The Work of an Instructor in the American Museum of Natural History," whose work lay especially with children and teachers. There is a note on a "Conference on Indian Museums" at which eleven governments or states were represented and a variety of topics discussed.

The Zoological Society Bulletin for April is an Aquarium Number, devoted to things aquatic. It contains a description of "The Bermuda Aquarium," tells of "Frogs and Frog Raising," of the "Water-throwing Habit of Fishes in the New York Aquarium," of "The Solution of the Carp Problem" and "Angling and Water Pollution." Finally there is "A Photographic Study of the Ghost Crab."

The Museum News, of the Brooklyn Institute, is mainly devoted to a "Guide to the Exhibits Illustrating Evolution and the Preservation of Animals" and a "Guide to the Trees and Important Shrubs of Bedford Park."

The Bulletin of the Charleston Museum announces the beginning of a collection to

illustrate the mineralogy of the middle and southern Atlantic states, to be known as the "Piedmont Mineral Collection."

BOTANICAL NOTES

It now turns out that the big cactus so common in Arizona, and which is a foot or so thick, and from fifty to sixty feet in height, is not a *Cereus* as had always been supposed. Under this generic name it had been known in books and reports as *C. giganteus*. A recent careful study of this plant by Drs. Britton and Rose has convinced them that its reference to this genus by Engelmann was erroneous, and they find that it is the type of a new and hitherto undescribed genus, which they name *Carnegiea* (*Jour. N. Y. Bot. Gard.*, Nov., 1908). Accordingly this striking cactus is hereafter to be known under the name of *Carnegiea gigantea* (Engelm.) Britt. and Rose.

ANOTHER genus has been segregated from *Cereus*, to which the name *Harrisia* has been given by Dr. Britton (*Bull. Torr. Bot. Club*, Dec., 1908). Three species from Cuba and Jamaica are now referred to this genus, and five new species from Cuba, Porto Rico, Haiti and the Bahamas are added.

A MORPHOLOGICAL paper of much more than ordinary importance recently appeared in the *Transactions of the Connecticut Academy of Arts and Sciences* (Vol. 14, pp. 59 to 170), under the title of "The Morphology of *Ruppia maritima*," by Dr. A. H. Graves. This plant is a slender branching aquatic, grass-like in appearance and belonging to the family *Potamogetonaceae*, which contains other genera and species of "pondweeds." After a morphological and ecological study of the vegetative organs, the reproductive organs are taken up in a most satisfactory manner, followed by a study of embryo, fruit, seed and seedling. Thirty-three text illustrations and fifteen large, full-page plates with 121 figures help to elucidate the descriptions. A bibliography of 98 titles closes the paper. In his closing chapter devoted to a summary of the relationships of *Ruppia* to other Potamo-

tonaceae the author finds evidence of reduction from "some form similar to the present submerged *Potamogetons*, with *Zonichellia* and *Althenia* serving as examples of still further reduction."

In the *Botanische Zeitung* for November 1, 1908, H. Bruchmann's paper, "Das Prothallium von *Lycopodium complanatum* L." adds materially to our knowledge of the gametophyte generation of this species. The tissues of the erect, tuberous gametophyte are shown to consist of a rhizoid-bearing epidermis; a layer containing endophytes; a layer of radially arranged palisade cells, and a large-celled central mass of parenchyma. Branching occurs, giving rise to increased areas for the sexual organs. Some of these prothallia are unisexual and others bisexual. The sexual organs are crowded into dense masses at the summit of the prothallium and are of the usual type of structure.

ALBERT MANN, expert in charge of special barley investigations in the Bureau of Plant Industry of the U. S. Department of Agriculture, makes a preliminary report of the results of his study of the problems of how to recognize the best grades of barley (Circular No. 16, issued November 25, 1908) in which he finds that "the diastatic and cytatic starch ferments are wholly the product of the scutellum and are secreted by its outer layer," and that there is so little of these ferments found in the starch cells that "it is practically negligible." Furthermore, "the aleuron layer has nothing whatever to do with this process," namely, the change of starch into a soluble form for absorption by the embryo, which is identical with what takes place in "malting." Hence the scutellum is the "malting organ," and that barley is best for malting purposes that contains the largest scutellum in the grain.

THE UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

SOME GEOLOGICAL PROBLEMS

AMONG the larger problems in the geology of eastern North America which to-day claim

attention are: the determination of the eastward and southeastward extension in their metamorphosed condition of the less altered rocks of the Hudson Valley and the satisfactory separation from these of the pre-Cambrian; as well as the separation and correlation of the divisions of the latter, if such exist.

J. D. Dana early essayed to show the continuity of the limestones and schists of the New York-Connecticut border with those of Westchester County, New York. F. J. H. Merrill took up the question later and reached practically the same conclusions. The work of Cook in New Jersey had shown how intimately the lower Paleozoics are involved in the Highlands of that state. Many of the facts seemed to point to a oneness in age of much of this limestone, schist and slate with the unaltered rocks to the north and west in the Hudson Valley and on the flanks of the Highlands.

The continuity of these rocks over large areas has been suggested and assumed rather than proved. Notwithstanding this they form a part of the same general problem, and any assumption regarding the age of one portion of this belt makes more imperative the need of better establishing the principles that will apply to the region as a whole. Any suggestion of incorrectness in age of any part raises the whole question to the fore.

Great uncertainty prevails in the minds of the Connecticut geologists as to the age of the greatly injected, disturbed and altered schists and limestones in the western part of that state. Manifestly any reasonable interrogation regarding the generally assumed age of the limestones and schists of southeastern New York is of great interest. The recent conservative suggestion of Berkey that the Inwood limestone and Manhattan schist are of pre-Cambrian age is a case in point.

The work of Hitchcock and Emerson in Massachusetts, that of Percival, Dana and the Connecticut Survey in Connecticut, and that of Mather, Dana, Merrill and Berkey in New York has done much to unravel the complicated geology of this region; but much confessedly awaits solution. The problem is to a great extent a structural one and is complicated through metamorphism by igneous intrusion.

Limestones are known in the pre-Cambrian rocks of Massachusetts, southeastern New York and New Jersey in the proximity of limestones of younger age. The uncertainty is not at this point, but as to which is which. The work of Cook, Britton, Nason and Bayley does not leave us clear as to what is assignable to the pre-Cambrian and what to the Paleozoic in the Highlands of New Jersey. The New York geologists are working at this problem, and the New England geologists will doubtless take the subject up again in the near future.

Much doubtless depends upon the success we may attain in correlating areas with one another as well as in establishing principles that will fit them all, and to what extent such a thesis as may be drawn up can be supported

by actual evidence, or reasonable inference, or both. With these general principles our interpretations of specific phenomena must fit if the principles are to stand.

*The Geology of Dutchess County, New York.*¹

The study of these problems reasonably begins with the examination of the least altered strata of the Hudson Valley. These strata, showing continuously increasing metamorphism as they are traced eastward, are well displayed in Dutchess County. Field work in this county reveals that the metamorphism approaches the character of a function of the distance of the strata from the Hudson River. The increment by which the metamorphism approaches a given degree varies in value, but apparently always is greater per unit distance as one approaches the southern part of the county. The fact that the pre-Cambrian rocks cut through the southeastern and southern portion of the county indicates that the degree of metamorphism may, in a measure, be directly connected with the proximity of the Highland mass.

The accompanying generalized sketch map is not intended to show the details of the areal geology of southeastern New York but rather to show pictorially the character of the general problem. It is based upon personal work in Dutchess County, particularly in the Poughkeepsie quadrangle, and upon the maps of Dana, Smock, Merrill and Berkey.

The north and south continuity of the western limestone belt (Barnegate or Wappinger) of Dutchess County was shown by W. B. Dwight. The identity of the eastern so-called Millerton-Fishkill belt with the Wappinger was proved for its northern or Millerton portion by the same worker. Recent work by the writer in the southern portion of the eastern belt, the Fishkill limestone, shows conclusively by the discoveries of fossils the presence of Georgian and Beekmantown terranes within this formation.

While considerably more metamorphosed than the Wappinger the alteration of the eastern limestone has not obliterated the

¹ Published with the consent of the New York State Geologist.

evidence of its age. The identity of the northern and southern portions of this belt is thus shown, and the eastward metamorphosed extension of the rocks of the Wappinger belt is likewise demonstrated. The intrarelationships of the western Wappinger are in some cases duplicated in part in the eastern belt. With these facts in mind the shading on the map is designed to show the gradation in metamorphism to the eastward.

To the east and south on the map are extensive areas of limestone and schist, for the most part left unmarked and unbounded, the satisfactory proof of the age of which awaits demonstration. Smaller patches not represented on the map, more intricately involved and often associated with igneous rocks, are scattered here and there in the Highlands. The great complex extends eastward into Connecticut, and southwestward into New Jersey, and has its representatives to the north in Vermont and Massachusetts. That it is a puzzling area is stating the case mildly. It must be attacked with a mind open for the reception of data bearing on the question of the possible genetic identity of extensive and disconnected masses or for the consideration of features that point the other way. The structure of the region must be unraveled and the earlier relationships of the component rocks restored. Moreover, it may be considered an open question, if with the changes that the pre-Cambrian rocks had early undergone, the later deformations and metamorphic agencies would not have produced a relatively greater alteration in the younger rocks.

It is purposed to discuss more fully certain features of the general problem in a forthcoming report on the geology of the Poughkeepsie quadrangle.

AMHERST, MASS. •

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION G—BOTANY

SECTION G of the American Association for the Advancement of Science met during convocation week at Baltimore, the sessions being held at the Eastern High School. The attendance of botanists

was unusually large and representative, and so many papers were offered for presentation that it was found necessary to divide into subsections. In Subsection A were presented the papers in morphology, physiology, ecology and taxonomy, while the papers in pathology were presented in Subsection B. Vice-president Richards presided over Subsection A, and Dr. F. L. Stevens, of the North Carolina College of Agriculture and Mechanic Arts, was chosen by the section to preside over Subsection B. As at the Chicago meeting the program of the section interlocked with that of the Botanical Society of America, so that program conflicts were reduced to a minimum. The address of the retiring vice-president, Professor Charles E. Beesey, on "The Phyletic Idea in Taxonomy," has been published in full in SCIENCE.

The following officers were chosen:

Vice-president—Professor D. P. Penhallow, McGill University, Montreal, Canada.

Member of the Council—Joseph N. Rose, U. S. National Museum, Washington, D. C.

Member of the Sectional Committee (five years)—Dr. D. T. MacDougal, Carnegie Institution, Tucson, Ariz.

Member of the General Committee—Professor Aven Nelson, University of Wyoming, Laramie, Wyo.

In view of the increasing difficulty of arranging the program in an equitable manner, the sectional committee appointed the retiring vice-president, Professor H. M. Richards, the incoming vice-president, Professor D. P. Penhallow, and the secretary, Dr. Henry C. Cowles, as a special program committee for the Boston meeting. In view of the coming meeting of the British Association at Winnipeg, the choice of a Canadian botanist for the vice-presidency of the section is regarded as most fortunate, and although no specific action was taken by the section at Baltimore, it was the general consensus of opinion that the American botanists should do all in their power to make the sojourn of the British botanists in America pleasant and profitable.

Abstracts of the technical papers presented at Baltimore follow, arranged in the order given in the respective subsections:

SUBSECTION A

Bog Toxins and their Effect upon Soils: ALFRED DACHNOWSKI, Ohio State University, Columbus, Ohio.

In a previous communication (*Bot. Gaz.*, 46: 180-143, 1908) attention was called to experi-

mental data showing that the inhibiting factors of bog conditions are in part due to the presence of injurious toxic water-soluble substances, reactions of the plants themselves, that such toxicity can be corrected by various methods, and that the plants grown in solutions thus treated show not only accelerated growth and an increase in transpiration, but also an increase in the green and dry weights of the plants.

Further experiments were undertaken to determine whether the toxins of bog water which are harmful to agricultural plants in water cultures are injurious also to plants growing in soil. A series of soils, ranging from pure quartz, sand and clay to humus were infected by shaking each with bog water, and filtering off the solutions. The results of these experiments indicate: (1) that the bog solutions thus treated become highly beneficial, (2) that soils absorb the toxins present in bog water, (3) that the soils are infected when treated in this manner and cease to yield a normal growth of plants when compared with similar soils serving as controls.

Initiating Licheno-ecologic Studies in the Kentucky Mountains: BRUCE FINK, Miami University, Oxford, O.

The writer has long felt that most of the problems of lichen ecology require an unusually long time for their solution and during the past few months has been able to initiate such studies in two places with a view to continuing the work begun through many years. The work in the Kentucky mountains was done on the forest reserve of Berea College, five miles from Berea, Ky. This locality in the foot-hills of the Cumberland Mountains was selected because the area is to remain undisturbed. Thirty-one areas of varying size and form were marked off, some of them left undisturbed after taking careful notes of the size and condition of development of the lichens within them, others denuded to a considerable depth below the surface of the soil or rock, while on others the plants were only partially destroyed, the object being to watch the rate of growth, invasion, regeneration, etc. The areas were numbered and dated, and were selected in groups so that the study of ecologic factors to follow with instruments may be facilitated as much as possible.

Descriptions of Species of Opuntia: DAVID GRIFFITHS, U. S. Department of Agriculture, Washington, D. C.

An effort was made in the paper to show the relative value of diagnostic characters in this group of plants, and to show how different con-

ditions radically affect these characters. A scale of points is made out to show a proposed sequence in descriptive literature. Stress was placed upon the necessity of field studies and descriptions drawn therein which shall describe the entire plant instead of a terminal joint or two, as has usually been done.

Physiological Studies on the Hymenophyllaceæ:

FORREST SHREVE, Carnegie Desert Laboratory, Tucson, Ariz.

Both physiological and anatomical evidence has been obtained to show that the leaves are the principal water-absorbing surfaces, and that there is very limited conduction of water in the vessels. Most Hymenophyllaceæ are capable of withstanding total submergence in well-aerated water for one month. Fragments of leaves with as few as ten cells are capable of maintaining normal appearance in dilute nutrient solutions for over one month. Most Hymenophyllaceæ are incapable of enduring a continued humidity as low as 60 per cent. Several hairy forms are able to endure low humidities of brief duration, and even occasional insolation. These forms are capable of surviving without liquid water if kept in air of over 90 per cent. humidity, and will continue to grow under these conditions. Isolated leaves show an ability to gain steadily in weight when kept in moist air, whereas controls killed in various reagents lost weights as did also the leaves of other species without hairs.

The Life History of Griffithsia Bornetiana: I. F. LEWIS, Randolph-Macon College, Ashland, Va.

The vegetative structures, tetraspores, antheridia, procarys and cystocarys were described in detail, as well as the germination of the spores and the development of the sporlings. Antheridia, cystocarys and tetraspores occur on separate individuals which are almost identical in vegetative structure. The size, shape and arrangement of the cells are the same in the different forms, as are also the size of the nuclei and the number of nuclei in each cell. In mitosis, however, the nuclei of the sexual plants show seven chromosomes, and the nuclei of the tetrasporic plants about twice that number. The reduction of the number of chromosomes takes place in the two divisions in the tetraspore mother cell. The double number is restored by the union of the gametes. The conclusion is drawn that the carpospores, on germination, give rise to tetrasporic plants and the tetraspores to sexual plants. In the alternation of generations thus arising, the sexual plants are to be considered as forming the "x-genera-

tion," while the "2x-generation" comprises the sporogenous cells of the cystocarp and the entire tetrasporic plant. It seems hardly likely, however, that the tetrasporic plants are analogous, save in the number of chromosomes, to the sporophyte of the archegoniates.

Vegetative Reproduction by Induced Root-regeneration in the Guayule: FRANCIS E. LLOYD, Alabama Polytechnic Institute, Auburn, Ala.

Parthenium argentatum (the Mexican guayule) and *P. incanum* (the Mexican mariola) are two woody perennials belonging to the Compositæ and are found in the northern part of the central plateau of Mexico. A comparison of these two species discloses certain differences in the methods of vegetative reproduction which have already been described by the writer. These differences appear to be quite constant in nature. It is, however, possible by experimental methods to force the guayule (*Parthenium argentatum*) to adopt the method of vegetative reproduction which is normally followed by the mariola (*Parthenium incanum*). The paper, of which this is an abstract, describes the experimental conditions and the results obtained.

The Morphology of the Peridial Cells in the Roestelia: FRANK D. KERN, Purdue University, Lafayette, Ind.

The value of the sculpturing on the peridial cells as a specific character in defining the species of *Roestelia* has already been ably pointed out by Dr. Ed. Fischer and a number of the American forms have been figured and described by him. Aside from the surface markings there are a number of other features about the peridial cells which are worthy of consideration. It is for the purpose of setting forth the microscopical structure with some detail that this paper is presented. The part played by the peridial cell in making the different appearance between the forms of *Roestelia* and *Æcidium* is discussed. The chief attention, however, is given to the various types of cells and to an explanation of the terms used in describing them. Concrete examples, including many little-known species in addition to the more common ones, are given, together with a number of illustrations.

The Effect of Certain Salts upon Transpiration and Growth in Wheat: HOWARD SPRAGUE REED, Virginia Polytechnic Institute, Blacksburg, Va.

An investigation has been made of the effect of some chemical compounds upon the amount of transpiration per unit of growth in wheat plants. The results are expressed in terms of the units of

water transpired per unit of increase in plant substance and by curves which show graphically the increments in transpiration and growth in comparison with control cultures. The data were obtained from several thousand wheat cultures grown in a variety of soils in paraffined wire pots, or in water cultures. Salts of sodium and potassium decrease the amount of water transpired per unit of growth, while salts of calcium and some other substances exert the opposite effect. Increasing the concentration of a salt usually exerts a different effect upon the curves of transpiration and of growth.

The Peg of the Cucurbits: WILLIAM CROCKER, University of Chicago, Chicago, Ill., and LEE I. KNIGHT, University of Illinois, Urbana, Ill.

The peg of the cucurbits is a parenchymatous outgrowth between the root and the stem which aids in the removal of the coat during germination. In the Hubbard squash and some other forms all seedlings produce ring-like pegs approximately equal on all sides (or at least on the two broader faces) if arching and contact are avoided. Under similar conditions in the Big Tom pumpkin and a number of other cucurbits a considerable per cent. of pegless seedlings appear. The functioning of this organ is possible only by its development on the concave side of the arch. The one-sided development is determined by the arching (including perhaps the growth strains preceding the actual arching) of the hypocotyl. Two stimuli aid in the production of the arch-contact of the coats and gravity. The contact of the coats is by far the more effective, for it will induce very sharp arching even against gravity. Gravity, independent of contact, gives strong enough arching to produce only one-sided pegs in all seedlings when the seeds are deviated 170° from the (point downward) vertical position. There is no evidence, contrary to the conclusion of Darwin, Noll and others, that gravity directly stimulates the lateral placement of this organ.

The Effect of Illuminating Gas and its Constituents on Carnations: LEE I. KNIGHT, University of Illinois, Urbana, Ill., and WILLIAM CROCKER, University of Chicago, Chicago, Ill.

The flowers of the carnation are extremely sensitive to traces of illuminating gas in the air, while the vegetation is comparatively resistant. In the Boston Market and pink Lawson varieties three days' exposure to 1 part in 40,000 kills the young buds and prevents the opening of those already showing the petals. The buds of medium age are considerably more resistant. In the same

varieties 1 part in 80,000 causes the closing of the open flowers upon twelve hours' exposure. This injury takes place directly on the bud or flower exposed and not indirectly through absorption by the roots. No chemical test is delicate enough to detect the least trace of illuminating gas in the air. Ethylene is even more fatal to the flowers of the carnation. Three days' exposure to 1 part in 1,000,000 prevents the opening of buds just showing the petals. Twelve hours' exposure to 1 part in 2,000,000 causes the closing of flowers already open. There is much evidence that indicates that the toxic limit of illuminating gas upon these flowers is determined by the ethylene it contains.

Types of Cactus Genera, 1753-1904: J. N. ROSE, Smithsonian Institution, Washington, D. C.

Linnaeus in 1753 referred all the cacti known at that time to one genus, which he called *Cactus*. Otto Kuntze in 1904, one hundred and fifty years afterwards, recognized but three genera; two of these, *Pterocactus* and *Pereskia*, are small or contain less than a dozen species, and hence the great mass of cacti are to-day to be found in the genus *Cactus* as understood by Linnaeus. This might indicate that Linnaeus's conclusions were good, but, as we all know, Otto Kuntze was a poor botanist, although he was a great bibliographer and doubtless did more than any one in modern time to stimulate botanical bibliography. Since Linnaeus's time 58 genera have been proposed.

What are the types of these genera? Naturalists are now all agreed that the type of a genus must be one of the original species in it. At the present time, however, we have two genera of cacti which do not contain any of the original species and of course are used in an entirely different sense from that which was first intended. These genera are *Pilocereus* and *Epiphyllum*.

Botanists are now pretty well agreed that we ought not to use a homonym of an older genus, and yet we have at the present time in cacti two names which come under this class, viz., (1) *Harriota* DC., 18—, while there is *Harriota* Adans, 1762, also a cactus; (2) *Mamillaria* Haw, 1812, while there is *Mamillaria* Stackh, 1809, a genus of algae.

Botanists are now pretty well agreed throughout the world that our nomenclature should begin with 1753 and that older names shall not displace Linnaean and post-Linnaean names, but at the present time we have in cacti one pre-Linnaean name which was not taken up until 1827, viz., *Melocactus*.

In the paper as presented there follows an alphabetical list of the genera of cacti, showing the date of publication of the genus, the number of original species and the names of the type species.

Some Variations and Hybrids of Enothera: R. R. GATES, University of Chicago, Chicago, Ill.

The extreme variant of *O. rubrinervis* which appeared¹ in my cultures is found to breed true to its peculiarity. The presence of red on the hypanthium and in excess on the sepals is correlated with its development in excess on the under surface of the rosette leaves. The same correlation exists in one of the types from *O. nanella* × *O. biennis*. The *O. biennis* in these crosses was from the type growing wild around the New York Botanical Garden. Seven plants germinated from this cross and five of them reached maturity. These were of two sorts, four of which belonged to one type. In this type the rosette leaves were long, rather narrow and pointed, like *O. rubrinervis*. The petioles were red above but more conspicuously so on the under surface. The buds were large like *O. Lamarckiana* and, like the extreme variant of *O. rubrinervis* mentioned, the hypanthium and sepals were red throughout. The excessive development of red pigment from a cross between two types, neither of which shows much red, is an unexpected result several explanations of which are possible. In the second type the buds were small and greenish, showing the *O. biennis* characters.

O. Lamarckiana × *O. biennis*. Nine plants matured, all of one type. The rosettes were very much like *O. nanella* × *O. biennis*, type I, but larger, and the petioles were bright red above but without red on the under surface. The buds showed the *O. biennis* characters, being small, with little red on the sepals and with a short style. The petals varied in size from that of *O. biennis* to intermediate between *O. biennis* and *O. Lamarckiana*.

These crosses were made by Dr. D. T. MacDougal, who presented the seeds to the writer for further cultures.

An interesting "combination type" appeared in a culture of English evening primroses which contain some of the mutants of *O. Lamarckiana* and in addition some new types. The type in question showed the characters of *O. Lamarckiana* in its rosette and stem leaves (absence of red) but the buds were typical *O. rubrinervis*. This combina-

¹ See SCIENCE, 27: 209, 1908.

tion type might be called *O. Lamarckiana rubri-nervis*.

On the Nature of the Fertile Spike in the Ophioglossaceæ: M. A. CHRYSLER, University of Maine, Orono, Me.

A study of the vascular system of the leaf in the Ophioglossaceæ supports the view that the fertile spike is to be regarded as two fused pinnae, viz., the two basal ones, which are comparable to the fertile pinnae of *Osmunda Claytoniana* and *Anemia* spp. It is found in *Botrychium* that the vascular supply of the fertile spike is double; that the two bundles arise from a curved leaf-trace, at or near its extremities, and higher up approximate but do not fuse. The vascular bundles of the sterile pinnae arise in a manner identical with that of the vascular bundles of the fertile spike. The mode of origin of the bundles of the fertile spike in each species of *Botrychium* examined may be paralleled by that seen in various genera of ferns, especially *Osmunda*. The genus *Ophioglossum* may be derived from the simpler species of *Botrychium*, while *Helminthostachys* shows certain complications. These facts point to the conclusion that the Ophioglossaceæ are to be regarded as a specialized family of ferns, rather than as a primitive order of pteridophytes.

Origin of Heterospory in Marsilea: C. H. SHATTUCK, Clemson College, S. C.

It is possible by means of a spray of cold water to kill the megaspores, which occur only in the oldest sporangia and then, putting the plant under good conditions, to mature sporocarps without megaspores. The greatest variation occurs when the megaspores and oldest microspores are blasted. Enlargement does not appear among the microspores when less than half the spores abort, and the surviving spores are larger the greater the amount of abortion. The mother cells may be checked in their development till the tapetal nuclei completely invest them. A perinium will then form around the four nuclei, sometimes enclosing them during the first and second mitoses. In such cases the sporangium invariably contains sixteen large bodies, each containing four nuclei. At other times when growth is less checked, the spores are more or less completely free and show great variation in size and shape.

The contest for supremacy among the young megaspores is very evident, many of them assuming considerable proportions, but one, centrally located, invariably secures the ascendancy. Sometimes the contest is very close between two or more members of the same tetrad. Very often the

surviving member will carry attached to its papilla the aborted members even to germination.

The enlarged microspores vary in size from eight to sixteen times that of the normal ones, the nucleus shifting from a central (normal) to an apical position as in the megaspores. As vacuolation is more extensive the shape of the nucleus also varies from the normal spherical form to the oval, and finally, in the largest to the meniscus shape in the megaspore.

In extreme cases of abortion in the microsporangia only one spore survives which is about sixteen times as large as the normal microspore. The aborted tetrads remain as in the megasporangium, but better developed, thus showing a sharper contest for supremacy.

In plants kept from fruiting till September 1, many microsporangia (by position) developed megaspores and a few megasporangia developed microspores. In such cases the megaspores were intermediate in size and were also more nearly the spherical shape of the microspores. A few cases were noted in which the megaspores did not develop a perinium but enlarged considerably and became gorged with starch. *Marsilea* may be made to repeat, under culture, all the phases in the development of heterospory reported by Williamson and Scott for both *Calamostachys Benneyana* and *C. Cosheana*.

Movements and Reactions of Fern Spermatozoids:

W. D. HOTT, Johns Hopkins University, Baltimore, Md.

The movements of the spermatozoids of ferns are complex and varied and depend on the conditions in which they are placed. When the conditions are unfavorable, they frequently reverse their direction of rotation, and they swing their anterior ends through a larger spiral and change their direction of movement more often than they do when in favorable conditions. The result of this is favorable to the organism in that they come in contact with a larger amount of the medium and so stand a better chance of reaching favorable conditions if these exist anywhere within the medium.

Different spermatozoids may react differently to the same stimulus at the same time, and the same spermatozoid may react differently to the same stimulus at different times. In some cases these differences in behavior can be ascribed to differences in physiological condition induced by different past experiences.

The cases where the movements have been sufficiently slow for exact analysis indicate that ori-

entation is attained by a series of random movements continued until a position favorable to the organism is reached, and not by a direct modification of the motor mechanism due to the local action of different concentrations of the medium on different portions of the body. This conclusion seems reasonably certain for negative reactions and probably for positive ones. The results obtained so far indicate that the movements and reactions of fern spermatozooids are of the same nature as those described for protozoa.

Some Aspects of the Mycorrhiza Problem: BENJAMIN C. GRUENBERG, DeWitt Clinton High School, New York, N. Y.

Mycorrhiza is found on the roots and underground stems in many families of plants. The identity of the fungus in the symbiosis has been determined in but few cases, and in these not always with certainty.

Many theories as to the relationship between fungus and phanerogam have been offered, but none fits all the facts. It is, however, not to be expected that the mycorrhiza has the same significance in all cases: in the different forms the relationship may be of different types, as nitrification, humus disintegration, water absorbing or storing, etc.

To the mycorrhizas occurring in plants free from chlorophyll, there has been ascribed the function of obtaining organic nutrients directly from the humus. In several species of *Corallorrhiza* examined there are present considerable quantities of starch, notwithstanding the entire absence of chlorophyll from the plants. The constituents of the humus that may yield carbohydrates, and the mechanism for the conversion of these materials into starch remain to be determined.

The solution of certain practical problems, as some in forestry, the transplanting of certain trees, tuberization, nitrification of the soil, etc., may have to wait upon the solution of some of the problems presented by the mycorrhiza.

The Morphology of Salvinia (preliminary):

WANDA M. PFEIFFER, University of Chicago, Chicago, Ill.

The early stages in the development of sporocarps are as described in Juranyi's "Ueber die Entwicklung der Sporangien und Sporen von *Salvinia natans*" (1873). In the young condition megasporocarps can be distinguished from microsporocarps only by the relatively smaller number of sporangia which they contain.

Later stages in the development of sporangia are very different from Juranyi's figures, since the

tapetum was never observed to become two-layered, although the tapetal cells were often multinucleate, and since in no case were there more than eight spore mother cells found in either megasporangium or microsporangium.

The behavior of abortive megasporos was as described by Heinricher, in so far as the position taken by such spores is concerned. The activity of these spores in the formation of the perineum, however, is extremely doubtful since this seems to be entirely built up by the activity of the large, deeply staining tapetal cells.

The relationship of *Azolla* and *Salvinia* is still an open question.

A Preliminary Account of Dioon spinulosum: CHARLES J. CHAMBERLAIN, University of Chicago, Chicago, Ill.²

Dioon spinulosum is a Mexican plant and has been known only from the leaves and some small trunks. The plant was found in abundance at Tierra Blanca and at Tuxtepec in March, 1908. The trunk is often six meters in height and occasionally reaches a height of 16 meters. The ovulate cones are very large, elongated ovoid, about 70 centimeters in length and about 30 centimeters in diameter. They often weigh 14 kilos. The sporophylls are comparatively much shorter than in *D. edule* and the seed much larger. The staminate cone is ovoid and measures about 21 × 10 centimeters. Material is being secured for an extended study.

Demonstration of Seedlings of Selaginella semper-virens: FRANCIS E. LLOYD, Alabama Polytechnic Institute, Auburn, Ala.

A Statistical Criterion for Species and Genera among the Bacteria: C. E. A. WINSLOW, Massachusetts Institute of Technology, Boston, Mass.

The existence of an almost infinite number of minute varieties has so far almost nullified any attempt at a natural classification of the bacteria. The vast numbers of generations which succeed each other in a short space of time, the absence of the swamping effect of amphimixis and the direct effect of the environment all help to make boundaries indistinct among these simple forms. The attempt has been made by the author and his colleagues to attack the problem by the statistical method, and the genera and species of the *Coccaceae* have been mapped out in the following way: A number of characters (mostly biochemical, for it is precisely along physiological lines that the bacteria have differentiated, as the higher forms

²Investigation prosecuted with the aid of a grant from the Botanical Society of America.

have varied along morphological ones) were measured in a series of 500 cultures by quantitative methods. The results when plotted and compared showed that, on the average, certain properties were notably correlated with each other, and with particular habitats. A parasitic and a saprophytic subfamily were clearly distinguished and within each subfamily several genera were established based on the general correlation of several independent properties. Within the genera each distinct modal point for a particular character was given specific rank. A species is therefore one of the centers about which the numerous existing varieties are grouped; and according to this method a species can be defined, not by the description of an individual, but only by the statistical study of a considerable series.

Effect of Age on the Venation of Leaves: H. M. BENEDICT, University of Cincinnati, Ohio.

The size of the small areas into which the leaves of dicotyls are divided by veinlets is affected by the age of the plant which bears the leaves. The younger the plant, the larger are these "vein islets."

That the size of these areas is not merely a measure of the available nutrition is shown by the fact that leaves from water-shoots which are usually of larger size than normal show smaller areas than smaller leaves from younger plants. Young and old plants growing under the same conditions of environment show the characteristic difference in venation.

As an example of the relation between age and size of areas, some data from a study of *Vitis vulpina* L. may be given. Ten mature leaves from different parts of each vine were taken; pieces 4 by 10 mm. were cut from the same part of each. These were arranged in series and photographed by transmitted light and the number and size of the areas calculated. Since the material was collected where it was impossible to cut down the vines the relative ages of the plants were judged by the diameters of the stems. Care was taken to select vines growing under the same conditions.

Vitis vulpina L.

Diameter of Vine	Average Area of Vein Smallest	Inlets in sq. mm. Largest	Average Area for Plant
1/4 inch	.49	.51	.50
1/2	.39	.41	.40
3/4	.36	.39	.37
1	.25	.29	.27
6	.12	.16	.14

Observations were made on *Ulmus americana*, *Castanea dentata*, *Quercus alba*, *Q. rubra*, *Tilia americana*, *Acer saccharinum*, *Fraxinus americana* and *Vitis bicolor*.

The Perennation of Ouscuta Epithymum Murr:

F. C. STEWART and G. T. FRENCH, New York Agricultural Experiment Station, Geneva, N. Y.

Although Kühn proved clover dodder to be perennial, by observations made in Germany forty years ago, the belief is still current that the species of *Ouscuta* are all annuals. With the exception of a brief note by the senior writer there is no record of any dodder in the United States surviving the winter in the thread form. Yet our observations indicate that *Ouscuta Epithymum* is frequently perennial. During the past three years this species has lived over winter in New York alfalfa fields, hibernating on the crowns of alfalfa, red clover and certain weeds. This is not accidental or occasional, but of common occurrence. In the writer's opinion it is the chief method by which dodder is carried over from one year to the next in New York alfalfa fields.

The First Generation Offspring of Oenothera lutea ♀

× *O. gigas* ♂: ANNE M. LUTZ, Carnegie Station for Experimental Evolution, Cold Spring Harbor, N. Y.

(No abstract is published, because the full paper has appeared in SCIENCE.)

The Plant Formations in Eastern Colorado, and

What They Indicate: H. L. SHANTZ, U. S. Department of Agriculture, Washington, D. C.

Three chief plant formations are recognized. They are discussed with respect to general appearance, types of root systems, the water relation of the soil, the influence of breaking the native sod, and the changes which bring about secondary and primary succession.

Notes on the Anatomy of Juncus (preliminary):

AMON B. FLOWMAN, Beaver, Pa.

In their minute anatomy the Juncaceae are strikingly similar to the more aerenchymatous representatives of the Cyperaceae, such as *Dulichium*, *Eleocharis* and the limicolous species of *Scirpus*. The central cylinder of the rhizome shows typical amphivasal fibrovascular bundles, which are more numerous and more highly developed in those species of which the rhizomes are short and compact. In the aerial stems showing nodes, the nodal complex is similar to that in *Dulichium*. The reproductive axis contains only simple collateral bundles, arranged in the typical dicotyledonous order.

Are Alpine Plants exposed to Increased Evaporation? CHARLES H. SHAW, Ambler, Pa.

Schimper, Flahault, Schroeter and others lay considerable emphasis on the fact that alpine plants are exposed to more rapid evaporation. Their statements appear to rest on the fact that air movement increases and pressure decreases with altitude, and upon instances of apparent rapid drying, and upon the xerophilous character of many alpine plants.

During the summer of 1908 two series of porous cup atmometers were set up in the Selkirks at altitudes ranging from 800 to 2,788 meters. The stations from 800 to 1,700 meters (first series) were on the same hillside, had the same exposure, and were separated by a total horizontal distance of less than one kilometer. Those from 1,800 to 2,788 meters (second series) were located as far as possible with similar exposure on Mt. Grizzly, and included a horizontal distance of about one and a half kilometers.

Two stations were chosen at each altitude, since a substantial agreement would afford a test of the reliability of the scheme. The instruments of the first series were in continuous operation twelve weeks and those of the second series, for shorter periods. The weather was unusually favorable, there being little rain, clouds or frost during a term of seven weeks. Weekly readings were taken. In most cases the instruments of the several pairs gave approximately the same result.

The maximum in every case was found at the second station, at 1,100 meters altitude. At increasing altitudes, there was a gradual and irregular diminution.

The results of the first series appear to be unquestionable, as also a certain portion of the second series. Taken together they seem to exclude, so far as these mountains are concerned, the idea that evaporation increases with altitude.

Possibly the standard writers may have overlooked the part played by temperature, which is a factor in the evaporation rate, and might more than counterbalance the results of the other two factors.

The above data represent only weekly totals. The possibility of excessive evaporation at high altitudes during certain portions of the day remains to be studied.

Mitosis in Oedogonium. A. H. TUTTLE, University of Virginia, Charlottesville, Va.

A brief review was given of the work of previous observers, and a statement of facts that ap-

pear to have been overlooked by them, or whose significance has not been noted.

Attention was particularly directed to the change in size and the marked change in form of the dividing nucleus; and, in addition, to the persistence of a distinct nuclear contour until a very late stage in the anaphase, also to noteworthy features in the mode of formation of the chromosomes, and in their behavior before, during and after splitting. Facts of importance regarding the formation and persistence of the achromatic figure were also presented, with others pertaining to the behavior of the daughter nuclei.

Preliminary Notice of Physiological Studies on Papaver somniferum. R. H. TRUE and W. W. STOCKBERGER, U. S. Department of Agriculture, Washington, D. C.

This paper discusses some studies made on the opium poppy, showing the distribution of oxidizing enzymes in the plant, the distribution of morphin and the relation of morphin production to oxygen.

The following papers were read by title:

Orientation of the Cotyledon of Wheat and Corn Seedlings Stimulated by Light. S. O. MAEST, Woman's College, Baltimore, Md.

Some Fundamental Errors in Botanical Teaching. E. C. JEFFREY, Harvard University, Cambridge, Mass.

Methods of Demonstrating the Oxidizing Power of Roots. HOWARD S. REED, Virginia Polytechnic Institute, Blacksburg, Va.

The Collection and Storage of Tree Seed. HUGH P. BAKER, Pennsylvania State College, State College, Pa.

Preliminary Report of the Result of Observations on the Relation of Evaporation to the Treelessness of the Prairies. BOHUMIL SHIMEK, University of Iowa, Iowa City, Ia.

A Summer Laboratory for Mountain Botany in Colorado. FRANCIS RAMALEY and W. W. ROBINS, University of Colorado, Boulder, Colo.

The Morphology and Development of the Oystercarp in Callithamnion Baileyi. R. P. HINSHARD, Mississippi Agricultural Experiment Station, Agricultural College, Miss.

SUBSECTION B

Two North Carolina Plant Diseases: Hypochnose of Apple and Colletotrichose of Fig. F. L. STEVENS and J. G. HALL, North Carolina College of Agriculture and Mechanic Arts, West Raleigh, N. C.

Hypochnose of apple, pear and quince, which is widely distributed throughout the United States,

but of which the causal fungus has not been before recognized except by Noack in Brazil, is described and notes on its geographical distribution given. Colletotrichose of the fig, *Ficus Carica*, is described and its causal fungus, *Colletotrichum Carica* n. sp., characterized.

A Bacterial Rot of the Muskmelon: N. J. GIDDINGS, University of Vermont, Burlington, Vt. (Read by L. R. Jones.)

One fourth of the fruit in a field of Montreal muskmelons at St. Albans, Vt., was ruined by soft rot in the autumn of 1907. This has been proved to be due to a new species of *Bacillus* which will be described in detail and named in the next Annual Report of the Vermont Experiment Station. Its characters in brief summary follow: 1-1.7 μ by .6-.9 μ . Actively motile by 4-8 peritrichic flagella. No endospores; not stained by Gram's method.

(Gelatin cultures at 20° C., others at 30° C.)

Nutrient broth: Strong clouding in 24 hours; no pellicle or ring formation; slight sediment. Agar stroke: abundant, slightly spreading, contoured, slimy, glistening, translucent-opalescent, growth, umbilicate in elevation. Agar stab: filiform. Agar plate: colonies round or amoeboid. Gelatin stab: infundibuliform liquefaction in two days. Milk: coagulation and some separation in two days; acid production of + 55 in twenty-one days. Fermentation broths: growth in closed arm in saccharose, dextrose, maltose, lactose, mannite, urea, asparagin, not in glycerin. Vegetables rotted: muskmelon, citron, carrot, potato, beet, turnip. Indol production: slight. Nitrate reduction: abundant. Acid production: slight from carbohydrate broths; pronounced from milk. Ammonia production: strong from asparagin. Gas: slight from asparagin; abundant from milk. Over 99 per cent. of gas from milk was CO₂.

The White Pine Blight: PERLEY SPAULDING, U. S. Department of Agriculture, Washington, D. C.

This popular term includes several well-marked and distinct diseases: a leaf blight accompanied by *Septoria parasitica*, two leaf diseases caused by *Lophodermium brachysporum* and *Hypodermia lineare*, a leaf and twig blight caused by winter freezing and a twig blight probably caused by insects.

Some Toxic Properties of Tannic Acid: MEL T. COOK, Agricultural Experiment Station, Newark, Del.

Within recent years a great deal of work has been done in growing fungi on substances con-

taining different chemicals and in studying the responses to the different stimuli. The series of experiments of which this is a part proposes to treat certain fungi with substances which occur in considerable quantities in the host plants. Tannic acid was selected as the first of these substances because it is so widely distributed and occurs in such great abundance, also because of its occurrence in abnormal growths. It is by no means well understood and is probably somewhat different in different families, genera and species. It has been studied by the chemists and pharmacologists but neglected by the botanists. It is frequently referred to as a waste product, although it is sometimes asserted that it may afford a protection against the attacks of insects, fungi, etc. It has been used to some extent as a germicide and fungicide.

This study has been divided into five series of experiments as follows:

First Series.—A study of the histology of pathological tissues; not treated in this paper.

Second Series.—The growing of fungi in pure media and in the same media to which has been added varying percentages of tannic acid. *Heterosporium*, *Ascochyta*, *Macrosporium*, *Phyllosticta* and *Rhizoctonia* are checked by small percentages of tannic acid. *Glauosporium*, *Colletotrichum*, *Cladosporium*, *Fusarium* and *Sphaeropsis* were retarded in most cases, but in some instances were stimulated by small percentages of tannic acid. *Alternaria*, *Sclerotinia*, *Necrospora* are stimulated by amounts not exceeding two fifths per cent. Those which are most strictly parasitic are more sensitive to tannic acid than those which are facultative saprophytes. A number of saprophytic forms were also used and were found to be stimulated by or at least to tolerate large quantities of tannic acid in most cases; this was especially true of wood fungi.

Third Series.—Consisted of growing fungi surrounded by barriers of tannic acid. Briefly discussed.

Fourth Series.—Consisted in treatment of fungi with varying percentages of tannic acid for varying periods of time and then placing them under favorable conditions for growth. In most cases the fungi were uninjured by this treatment.

Fifth Series.—Consisted in growing fungi through sheets of cork. Most fungi will penetrate cork readily if the tannin has been removed.

The Present Status of Rice Blast: HAYEN METCALF, U. S. Department of Agriculture, Washington, D. C.

The parasitism of a fungus of the genus *Piricularia*, announced before this section in 1906, and since confirmed by Fulton, has been verified by over six hundred inoculations. The parasite is a *vera causa*, although the occurrence of blast is enormously favored by a soil rich in nitrogen. It is doubtful whether a specific designation of the fungus can be made without revising the genus. The speaker's investigations in Italy in 1908 indicated the identity of blast with *brusone*, and tended to confirm the views of Farneti on the etiology of the disease. As *brusone* has already been shown to be identical with the *imochi-byo* of Japan and the *omo-mentek* of Java, the evidence is strong that blast is a world-wide disease which has only recently reached America. In Italy the disease is practically under control by use of resistant varieties of rice. These were imported by the author and will be tested in 1909.

A Few Diseases of Bamboo and Sedge: FLORA W. PATTERSON and VERA K. CHARLES, U. S. Department of Agriculture, Washington, D. C.

This paper discusses a few diseases occurring upon these hosts, their morphology, systematic position and especially their economic significance in relation to future foreign introductions. It includes pathological and histological notes on species previously known to cause diseases and the description of a new genus.

Specimens of diseased bamboo, and specimens of diseased sedge with water-color illustrations of the latter, accompanied the presentation of the paper.

Pathological Notes Concerning a Few Ornamental Plants: FLORA W. PATTERSON and VERA K. CHARLES, U. S. Department of Agriculture, Washington, D. C.

This paper discusses the occurrence of a *Botrytis* disease of peony and chrysanthemum, including cultural notes and statements as to preventive treatment.

A new disease on *Cyclamen* caused by *Colletotrichum* is described together with cultural notes on its development.

Necrosis of the Grape: DONALD REDDICK, New York State College of Agriculture, Cornell University, Ithaca, N. Y.

Necrosis is a very common fungous disease of the cultivated *Labrusca* varieties of grape in New York state, and it occurs also on the white scuppernon grape in Alabama.

The disease may be recognized as follows:

Vines trimmed and tied up which fail to put out shoots; a dwarfing of shoots and leaves and a light setting of fruit; leaves reduced in size, crimped about the margin and chlorotic; the sudden wilting of vines in late summer; the presence of longitudinally ribbed excrescences or tuberculous masses on any part of the stem; small, black, slightly sunken lesions on the green shoots.

This disease is caused by *Fusacoccum viticolum* n. sp. The fungus causes a dry rot in the stem, the effects on other parts, except lesions on the shoots, being purely physiological.

The fungus has been isolated from the interior of many diseased stems, from lesions on green shoots and from spores developed in stromata on the surface of dead parts. Pathogenicity is not yet absolutely demonstrated, but this is the only organism constantly associated with such conditions. The most serious effects of the fungus are found in very young vineyards and it is thought that this is due to the use of diseased cuttings for stock.

Root crowns are often free from disease and this affords a means of control, viz., by renewal with a sprout from the root.

A Blight of Cultivated Ginseng caused by Alternaria Panax n. sp.: H. H. WHEZZEL, New York State College of Agriculture, Cornell University, Ithaca, N. Y.

The greater part of the million dollars' worth of ginseng now annually exported from the United States is grown under cultivation. Though but very recently brought under domestication, it is known to be subject to a number of diseases.

The most common and destructive disease is the so-called *Alternaria* blight. It is characterized by the appearance of brown cankers on the stems and large watery spots in the leaves which may eventually involve the entire leaf and top. Badly blighted plants appear as if drenched with boiling water.

The pathogenicity of the *Alternaria* constantly occurring in the lesions has been definitely determined by inoculation.

Experiments extending over three years have shown that it may be controlled by the thorough application of Bordeaux mixture.

On a Method of Developing Claviceps purpurea Tul. with Notes on Claviceps rubra n. sp.: H. H. WHEZZEL and DONALD REDDICK, New York State College of Agriculture, Cornell University, Ithaca, N. Y.

Early in August, 1907, sclerotia of *Claviceps*

were collected in heads of Volunteer rye, and of roadside timothy in Noble County, Ind. August 20, 1907, sclerotia on *Daactylis glomerata* were collected at Ithaca, N. Y., and, on August 23, on *Festuca elatior*. On the latter date these collections of sclerotia were encased separately in ordinary wire screening and placed on the ground under a grape arbor to mature. April 6, 1908, all were brought to the laboratory and placed on moist sand in a covered stender dish. April 18, 1908, a few sclerotia in all dishes were found with developing stromata. At this time the stromata on timothy were further advanced and were very evidently different. Stromata from ergot on rye had mature perithecia about May 1, while those on *Daactylis* and *Festuca elatior* were mature May 6. May 23 all had fruited and gone.

The *Claviceps* on rye, *Daactylis* and *Festuca* all belong to the same species, at least morphologically, i. e., *C. purpurea* Tul. A few sclerotia on *Phleum* unmistakably developed typical *C. purpurea*; most of them developed a *Claviceps* with much smaller stromata which are of an entirely different color, have fewer and more prominent perithecia, and these contain smaller spores. It seems to be an undescribed species. Careful search was made in June, 1908, for the sphaerial stage in the type locality but it was not found.

Some Little-known Diseases of Conifers found in Connection with a Disease Survey of our Western Forests: GEORGE GRANT HEDGCOCK, U. S. Department of Agriculture, Washington, D. C.

The disease survey of our western forests which is now being conducted by the Laboratory of Forest Pathology, although it has not passed the preliminary stage, has brought forth some interesting data concerning a number of wood-rotting fungi which may be properly classed as wound parasites. These cause great losses to the country by diminishing to a very considerable extent the available supply of mature timber. They do not occur uniformly in any given forest, but abound in certain favorable environmental conditions.

Echinodontium tinctorium is the cause of a destructive heart rot of living trees belonging to a number of species. It attacks the following species: *Abies nobilis* Lindl., *A. concolor* (Gord.) Parry, *A. grandis* Lindl., *A. lasiocarpa* (Hook) Nutt., *Tsuga heterophylla* (Raf.) Sargent and Nicot., *Picea Engelmanni* Engelm. In a few localities as high as sixty per cent. of *Abies* and nearly one hundred per cent. of *Tsuga* have been reported diseased by this fungus. The fungus usually

enters the heart wood of the trees attacked either through a broken limb, fire scars or other wound. The mycelium evidently secretes a solvent for wood fibers, since they are often entirely dissolved in the later stages of the rot produced by the disease. The sporophores contain a red pigment which is especially characteristic of this species. This is used by the Indians for making paint for facial decorations, etc. The red coloring matter in the pigment is insoluble in the ordinary solvents, with the exception of the alcohols, which apparently dissolve out a yellow color.

Fomes laricis attacks the heart wood of a number of species of conifers. The fungus gains entrance into the heart wood in the same manner as *Echinodontium*. It has been found on the following species: *Pinus ponderosa* Laws., *P. Murrayana* "Oreg. Com.," *P. Lambertiana* Dougl., *Larix occidentalis* Nutt. and *Pseudotsuga taxifolia* (Lam.) Britton. The effect of this fungus on the heart wood of trees is somewhat different from that of *Echinodontium*; it does not so completely dissolve the wood fibers, but apparently carbonizes them, causing the wood to break up into blocks or rectangular pieces. Large sheets of punk or tinder are formed by the mycelium adjacent to sporophores in later stages of the disease. The decayed wood is of a red-brown color, resembling very much that produced by *Fomes pinicola* (Sw.) Gill., which is frequently the cause of a sap-rot of mature conifers, but is rarely found fruiting on living trees. *Fomes laricis* usually forms sporophores on living trees, but may in case of very large trees consume the heart wood for years before it brings forth fruiting bodies. The white chalky sporophores are often of very great size. They have been powdered and used as a medicine in Europe for ages, and owing to the bitter taste of the substance of which they are composed, have been designated as the "quinine fungus."

Several other wood-rotting fungi of lesser importance have been found in various localities, a study of which will be undertaken later. In our disease survey work the investigation of such problems is not confined to the immediate study of the parasite, its effect on the host and remedial and preventative methods. It is our purpose in the future to collect data upon the conditions in the forest which make the trees of certain areas more subject to disease than those of others in the same locality. This involves a study of the physical conditions of those localities where disease is prevalent in order to find out how they

vary from the conditions in adjacent localities where the trees remain healthy.

The Present Treatment of Monotypic Genera of Fungi: C. L. SHEAR, U. S. Department of Agriculture, Washington, D. C.

The following seven monotypic genera of fungi, *Oosporium* Sacc., *Cryptosporium* Grev., *Cylindrosporium* Grev., *Isothea* Fr., *Nemaspora* Willd., *Septaria* Fr., *Sphaeropsis* Lev., selected at random from the Pyrenomycetes and Fungi Imperfecti are cited as examples of the present condition of the nomenclature of the fungi as represented in recent general systematic works such as Saccardo, "Sylloge Fungorum," Engler and Prantl, "Pflanzenfamilien," Rabenhorst's "Cryptogamenflora" and Ellis and Everhart's "North American Pyrenomycetes." The rule adopted by the international zoologists and the American botanists that a monotypic genus must always contain its monotype appears to receive no particular recognition. The original monotypes of the genera mentioned have been transferred to other genera of later date and the original generic names are now applied to other groups of species and frequently attributed to other authors. The desirability of recognizing the fixity of monotypic genera and genera having a species specifically designated as type is suggested as an essential part of the rules to be formulated by the section of the International Botanical Congress which is to consider the nomenclature of cellular cryptogams at its meeting at Brussels in 1910.

A Bacterial Disease of the Peach: JAMES BIRCH ROBEY, U. S. Department of Agriculture, Washington, D. C.

For the past three seasons the writer has made observations on a disease of peach leaves, twigs and fruit, evidently caused by a bacterium.

The form on the leaves is the commonest and most widespread. It causes somewhat angular purplish-brown spots one eighth to one fourth inch in diameter, which soon drop out, giving a shot-hole effect. Serious outbreaks of the disease cause a premature defoliation of the trees. This leaf spot was first seen by the writer on peach leaves collected in Georgia in 1903 by Mr. P. J. O'Gara, of the Department of Agriculture. During the same season Clinton observed a disease, evidently the same, in Connecticut and reported in the Report of the Connecticut Agricultural Experiment Station for 1903, Part IV., page 337. In 1906, 1907 and 1908 the writer found the disease to be prevalent throughout the south and middle west.

In August, 1906, pure cultures of an organism were obtained from the leaf spots and in the following spring inoculations made with this organism caused spots in all respects similar to those from which the bacterium was originally obtained. The same organism was again obtained in pure cultures from the spots which were artificially produced.

The disease on the twigs was first observed in 1907 at Siloam Springs, Ark. It kills the bark of young shoots, forming purplish-black, slightly sunken areas one eighth to one fourth inch wide, which may extend for two or three inches along the stem. In 1908 this twig disease was found in an orchard in Bentonville, Ark. Numerous sections through the youngest spots showed the presence of bacteria in large quantities and by the poured plate method cultures of an organism similar to that from which the leaf spots were obtained. No attempt has been made as yet to produce this form of the disease by inoculation.

The disease on the fruit is very characteristic. It was found in two orchards at Bentonville, Ark., during the past season. It causes a very small purplish spot over which the skin soon cracks, in either a straight or an angular way. The spots are usually very numerous (two hundred and fifty have been counted on one side of a peach), and often coalesce so that the cracks become continuous and extend for an inch or more. Sections through the smallest spots showed that bacteria were present in abundance and evidently the cause of the trouble.

Though not entirely proved, it is assumed that the three forms of the disease mentioned above are caused by *Bacterium pruni* Erw. Smith, which causes the bacterial black spot of the plum, for the following reasons: (1) the leaf spot of plums caused by *B. pruni* is very similar in appearance to that of the peach; (2) by inoculation with pure cultures of *B. pruni*, spots may be produced on peach leaves similar in all respects to those occurring naturally; (3) the organism isolated from the peach leaf spot and twig spot have the same cultural characteristics in all the different media in which they have been grown as *B. pruni*; (4) though the organism has not been obtained in pure cultures from the peach fruit spots, the megascopic and microscopical appearance of these spots is identical with the small spots on the plums, especially those which result from late infections.

The Cause of Trembles and Milk Sickness: E. L. MOSELEY, Sandusky High School, Sandusky, O.

Experiments made in 1908 confirm the conclusion reached after experimenting on various animals in 1905, viz., that *Eupatorium ageratoides* is the cause of trembles and milk sickness. A rabbit with four sucking young was fed with this plant, causing trembles in all of them. Two of the young were killed and cooked and fed to a cat, causing trembles. Milk from a cow with whose food *Eupatorium* leaves were mixed caused trembles in cats and rabbits. The milk was found to contain aluminum and an increased quantity of magnesium. The urine of a rabbit fed with the weed contained much aluminum. These substances exist in large quantities in the ash of the plant, the amount of magnesium differing in plants from different sources. Magnesium nitrate mixed with the food of a rabbit produced trembling. The symptoms of trembles observed by those who have lost stock from this cause are the same as result from aluminum and magnesium compounds when they get into the blood.

Peach Yellowa Disseminated by Nursery Trees:

J. L. PHILLIPS, Blacksburg, Va.

Peach pits and buds are sources of infection. The disease does not usually appear in nursery stock. It appears in orchards in the second and third years. Peach pits should be sold under certificate of inspection.

A New Anthracnose Attacking Certain Cereals and Grasses: THOMAS F. MANNS, Ohio Agricultural Experiment Station, Wooster, O. (Read by A. D. Selby.)

This paper stated briefly the results of culture investigations of a fungus described as *Colletotrichum cereale*, n. sp. This has been found to be present generally over the state of Ohio, attacking the spikes, culms and sheaths of rye, the culms and sheaths of wheat, oats, chess, orchard grass, timothy, red-top and blue-grass. Upon the cereals the attack is timed to the approaching maturity of the plant and produces marked shrivelling of the grain. The behavior of the fungus on different media is stated, and different illustrations are included.

A New Bacterial Disease of the Sugar-beet Leaf: NELLIE A. BROWN, U. S. Department of Agriculture, Washington, D. C.

Last summer a new disease of the sugar beet was observed in the beet fields in Utah and California by Dr. C. O. Townsend, pathologist in charge of sugar-beet investigations, Department of Agriculture, Washington, D. C., who sent material to his laboratory for investigation.

The leaves had dark brown, often black, irreg-

ular spots from 3 mm. to 1.5 cm. in diameter. They occurred on the petiole, midrib and larger veins. Occasionally the discoloration extended along a vein some distance and the tissue on either side was brown and dry. An organism was plated out of these spots without difficulty and found to be a schizomycete. Inoculations were made in the greenhouse and in the open field at Garland, Utah. The infection did not fail to take in any case.

So far as the work has been carried, the organism is infectious to the sugar-beet root, leaves of lettuce, sweet pepper, nasturtium, egg-plant and leaves and pod of the bean.

On agar plates the colonies are cream-white by reflected light, bluish in transmitted light, thin circular, rapid-growing, appearing in twenty-four hours. In three days the surrounding agar becomes a yellowish green color.

The organism liquefies gelatin, turns litmus milk-blue, does not grow on Cohn's solution, clouds bouillon in twenty-four hours, and is motile by means of one to three polar flagella. It occurs singly or in chains, the elements being short rods from 2 to 4 μ long and 1 to 1.5 μ wide, when grown in agar two days and stained with Loeffler's stain. It grows best at a temperature of about 28° C. and is not killed when kept at -2° C. for six days.

From spots produced by inoculation, the organism has been reisolated and the disease reproduced. One hundred per cent. of the inoculations have given positive results. Both young and old tissues are alike susceptible to the disease.

A New Bacterial Disease of Nasturtium: CLARA O. JAMIESON, U. S. Department of Agriculture, Washington, D. C.

In May, 1908, Dr. C. O. Townsend, pathologist in charge of sugar-beet investigations, Department of Agriculture, Washington, D. C., received a few diseased nasturtium leaves from Richmond, Va. The wilted and partly discolored leaves showed water-soaked-looking spots from 3 to 5 mm. in diameter. Investigation proved the disease to be due to a bacterial organism belonging to the genus *Bacterium*. Inoculations of healthy leaves produce small dark, watery areas, and the tissue within them discolors, shrivels and often breaks.

The bacterium is a short rod from 2 to 4 μ in length, occurring singly or in chains. The polar flagella vary from 1 to 3 μ . The organism has moderate vitality on culture media, clouds bouillon in 24 hours and grows rapidly on agar, appearing on poured plates as small round, bluish-

white colonies. The bacterium liquefies gelatin, gives an alkaline reaction in litmus milk and produces no gas in fermentation tubes containing peptone-water and 1 per cent. solutions of diffused sugars.

The organism is not killed when kept at a temperature of -2°C . for six days. It grows best on agar at about 25°C ., and its thermal death point, found by exposing ten minutes in nutrient solution, is between 49°C . and 50°C .

The bacterium is pathogenic on the leaves of sweet pea, lettuce, pepper and sugar-beet and on the leaves and pods of the bean.

Decay of Potatoes Due to Rhizopus nigricans:
W. A. OXTON, U. S. Department of Agriculture, Washington, D. C.

A study has been made by the Bureau of Plant Industry of potato diseases in the peat lands of San Joaquin County, Cal.

The most prevalent form of decay is a rapid soft rot, caused by *Rhizopus nigricans* Ehrdt. This is characterized by a dull-brown discoloration of the outer skin and a slight brown discoloration of the flesh, which when cut open soon oxidizes to a reddish-brown. The tissue becomes soft, owing to a solution of the cell walls, and on squeezing there is liberated an abundance of clear brown liquid. This feature has given the disease the local name of "leak" or "melters." There is no bad odor until the invasion of secondary saprophytes.

The large, hyaline, non-septate hyphae of the fungus are abundant in the tissue. No other organism occurs in the typical "leak." Pure cultures are readily obtained, and a similar decay may be produced by inoculation of sterile raw potatoes under suitable conditions of temperature and moisture. Differences were observed in the rate of decay produced by *Rhizopus* from different sources, that from potatoes producing decay in potatoes sooner than a culture from bread.

Rhizopus nigricans is a wound parasite, capable of affecting potatoes only through abrasions of the epidermis. It appears to spread most rapidly during the "sweat" following the digging of early potatoes in warm weather and gives no trouble after frost comes.

The same fungus causes a destructive rot of sweet potatoes, and will quickly liquefy apples and pears. *Rhizopus neoans* Mass., a related species, causes a decay of lily bulbs in Japan.

Some Devices to Facilitate Work in Plant Pathology: E. MEAD WILCOX, University of Nebraska, Lincoln, Nebraska.

The method recommended in this paper is, in brief, to arrange all of the material used in pathology work according to one method. It has been found very useful to arrange lantern slides, negatives, index cards, herbarium material and publications alphabetically by the scientific name of the diseased plant, with sub-headings for the several diseases. The herbarium specimens are kept in the ordinary envelopes, which are attached to cards arranged behind guide cards in a vertical file case. The color of the card indicates the part of the plant which is diseased. For example, on the green card would appear specimens of leaf disease, etc. The publications bearing on plant pathology are gathered together and bound by subjects; this necessitates in many cases the partial destruction of a larger publication containing articles on several subjects, but the result is a compact mass of literature on one subject.

The following papers were read by title:

The Spraying of Cedars for "Cedar Apples":
F. D. HEALD, University of Texas, Austin, Tex.

A Fusarium Disease of the Pansy: FREDERICK A. WOLF, University of Texas, Austin, Tex.

Studies in Sclerotinia; Sclerotinia fructigena (Pers.) Schröt.: J. M. READE, University of Georgia, Athens, Ga.

Experiments in the Production of an Anthracnose Resistant Clover: S. M. BAIN and S. H. ESSARY, University of Tennessee, Knoxville, Tenn.

Two Interesting Smuts: L. H. PAMMEL, Iowa Agricultural College, Ames, Ia.

HENRY C. COWLES,

SOCIETIES AND ACADEMIES

THE NEW YORK ACADEMY OF SCIENCES SECTION OF BIOLOGY

A REGULAR meeting of the section was held at the American Museum of Natural History, on March 8, 1909. In the absence of the chairman, Professor Bashford Dean presided for the evening. The following papers were read:

Genetic Relations of the Insectivora to other Orders of Mammals: Mr. W. K. GREGORY,

The Harpswell Biological Laboratory: Mr. MAX MORSE.

The speaker showed a series of slides illustrating the Harpswell region and environs. The laboratory was founded by Dr. J. S. Kingsley in 1898 in the little fishing village of South Harpswell, Maine, eighteen miles from Portland. The immediate region is rich in interesting forms of

animal and plant life which are peculiarly adapted to the use of the investigator. The laboratory offers no courses of instruction, being solely for the use of investigators. The old Tide-mill collecting ground and samples of some of the more important animals and plants to be found there, were illustrated. The geology of the Harpswell region has not been worked up and this presents interesting questions, especially in glacial geology. The speaker pointed out the advantages offered by the laboratory over those of our other marine stations.

Early Developmental Stages in Recent and Fossil Corals: Professor A. W. GRABAU.

Paleozoic corals show in their septal development a fundamental tetrameral plan. This is persistent in the earliest known forms, but becomes masked in later species by the secondary assumption of radiality. The development of mesenteries of modern Hexacoralla shows a similar order of appearance. Pairs of mesenteries develop in succession in bilateral disposition. From the position of the muscle strands they are either *dorsads* (musculature turned dorsal-ward) or *ventrads*. The first and second pairs are *ventrads*. The third (ventral directive) is a pair of *dorsads*, the fourth (dorsal directive) a pair of *ventrads*. The fifth and sixth pairs are *dorsads* forming with the first and second pairs four false pairs of "braces." After that the mesenteries appear in compound pairs, a pair of *dorsads* and one of *ventrads* appearing simultaneously. Thus in the corresponding inter-mesenterial spaces a *brace* of new mesenteries appears, the order being comparable even in detail to the order of appearance of the septa in the Paleozoic Tetracoralla.

A REGULAR meeting of the section was held at the American Museum of Natural History, on April 12, 1909. In the absence of Mr. Frank M. Chapman, chairman of the section, Professor Chas. L. Bristol presided. The following papers were read:

Final Report on the Exploration of the Fayûm in 1907: Professor HENRY F. OSBORN.

In the absence of Professor Osborn, this report was given by Mr. Walter Granger, of the American Museum of Natural History. The speaker stated that the collection obtained by the expedition has been prepared and proves to contain representatives of nearly all of the mammalian forms known from this region, together with several new genera and many species. Among the new forms are rodents, recorded for the first time

from these beds, and two peculiar small forms of uncertain ordinal positions. The collection contains many fine specimens of described species which add much to the previous knowledge of these interesting mammals. Doubt was expressed as to the relationships of the genus *Megalohyrax* to the Hyracoidea and *Mærittherium* to the Proboscidea. The speaker stated that the collection of 1907 is being increased through the efforts of a representative maintained in the Fayûm.

By chart and slides the geology of the region was illustrated, also the important topographic features and the method employed in prospecting and collecting the fossils.

Studies on Tissue Growth: Dr. CHAS. R. STOCKARD.

The Partulas of the Society Islands and the Problem of Isolation: Professor HENRY E. CRAMPTON.

The speaker presented some of the general results obtained during investigations in 1906, 1907 and 1908, dealing with the variations and distribution of terrestrial snails of the genus *Partula*, inhabiting the Society Islands. The geographical and physiographical conditions were described. The islands of this group are volcanic peaks of a partially submerged range; these peaks occur sometimes in contact, as in the double island of Tahiti, while others have greater or lesser distances between them. It is, therefore, possible to correlate the specific differences between the snails of different cones with the geographical proximity of the cones. As each island peak is furrowed more or less regularly by valleys and as the snails occur only in the moist bottomlands of these valleys, it is possible to correlate the degree of resemblance between the species of neighboring valleys with the degree of geographical isolation. In brief, such correlations are extraordinarily close, as in the case of the classic Achatinellidae of the Hawaiian Islands described by Gulick.

The varieties of snails growing in different valleys of one and the same island, or in different islands of the group, can not be regarded as produced in different environmental circumstances. Several illustrations were given which established this conclusion. The phenomena of mutation were observed in several islands. Finally the rôle of natural selection was determined to be a much restricted one in the case of these snails.

Secretary

AMERICAN MUSEUM OF
NATURAL HISTORY

THE ELISHA MITCHELL SCIENTIFIC SOCIETY OF THE
UNIVERSITY OF NORTH CAROLINA

THE 183d meeting of the society was held in Chemistry Hall, Tuesday, April 1909, at 7:30 P.M. The following papers were presented:

"The Linear Classification of the Cubic Surface," by Professor Archibald Henderson.

"Trichlorethylidenediphenamine Compounds," by Professor Alvin S. Wheeler.

ALVIN S. WHEELER,
Recording Secretary

THE AMERICAN CHEMICAL SOCIETY. NORTHEASTERN
SECTION

THE ninety-second regular meeting of the section was held at the Twentieth Century Club, Boston, on April 8. Professor W. D. Bancroft, of Cornell University, addressed the section upon "The Reversal of the Photographic Image." The speaker advanced a new theory to account for the appearance of a positive and of a second negative upon the development of over-exposed photographic plates, and showed how, by the aid of this theory, many obscure phenomena connected with reversal are capable of a simple explanation. Dr. H. W. Morse, of Harvard University, addressed the section upon "Some New Methods of Nitric Acid Manufacture." After describing the method of synthesis used in Norway, the speaker discussed in detail the "Ostwald Process" for the oxidation of ammonia to nitric acid by the air with platinum foil as the catalyzer.

KENNETH L. MARK,
Secretary

THE SCIENTIFIC SOCIETY OF NORTH DAKOTA

IN October of last year a general scientific society was organized with headquarters at the North Dakota Agricultural College and Experiment Station. Administration officers are as follows:

President—J. H. Shepperd, dean of agriculture.

First Vice-president—Linwood A. Brown, professor of pharmacy.

Second Vice-president—H. L. Bolley, professor of biology.

Secretary—Roe E. Remington, instructor in food chemistry.

The society meets fortnightly, and the following papers have been presented:

October 7—"Fixation of Nitrogen," Roe E. Remington.

October 21—"Weed Eradication by Means of Chemical Sprays," H. L. Bolley.

November 4—"The Geology of the Stump Lake Region," D. E. Willard.

November 18—"The Relation of some Recently Formulated Biological Principles to Plant Breeding," O. O. Churehill.

December 2—"Some Engineering Problems Connected with Water Filtration," R. H. Slocum.

December 16—"The Sanitary and Bacteriological purification of Water," T. D. Beckwith.

January 13—"Some New Productions in Plant Life," J. H. Shepperd.

January 27—"Denatured Alcohol, Manufacture and Uses," Grant J. Morton.

February 10—"Darwin and after Darwin," C. B. Walaron.

February 24—"Birds of North Dakota," W. B. Bell.

March 10—"Studies on Soil Toxins," J. W. Ince.

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

A SPECIAL meeting of the society was held on Tuesday, April 27, 1909, President Fewkes in the chair. The program consisted of a paper by Miss Frances Densmore entitled "The Study of Indian Music" based upon her own recent investigations among the Chippewa of Minnesota. She stated that the object of this study was to find by analysis what constitutes Indian song and musical performance and to make the results of the study available and clear to those who are not musicians but who are interested in the genuine progress of science. Her method of procedure is to make phonograph records of Indian songs, transcribe these, analyze both record and transcription, and tabulate the analyses in accordance with a definite system. Among the interesting results of this work Miss Densmore mentioned the fact that some songs were found to be melodic and some to be harmonic in structure, and also that the rhythm was most peculiar in songs intended to exert a mental influence such as "medicine" songs, certain Mide songs, and also songs intended to incite to war. The paper was illustrated by means of phonograph records and vocal selections to the accompaniment of a drum and the piano. An interesting discussion followed.

JOHN R. SWANTON,
Secretary

THE IONS OF THE ATMOSPHERE¹

As one of the results of the recent development of electrical science it is considered that throughout the air in its normal state, and in other gases in a similar condition, there exists a small number of molecules, or groups of molecules, which are distinguished from the vast host of their fellows in being electrified. Each of these electrified entities, whatever its structure, is called an ion, and of ions there are two main classes, the one containing those which are positively, the other those which are negatively, electrified. The notion of the ion, in this connection, arises from attempts to reach a simple description of the facts associated with the conduction of electricity through gases, and the hypothesis admirably fulfils its purpose.

The number of ions in the air can be greatly increased by exposing it to the influence of Röntgen rays, or to the radiations from radium or other radio-active bodies, and it is from investigations connected with this artificially produced ionization that most of our present knowledge of ions is derived. For the most interesting account of these researches I refer you to the address delivered before this section at Dunedin in 1904 by the present distinguished president of the association. For my immediate purpose I have to remind you of one result: in an electric field, in addition to the motion of molecular agitation shared by all the constituents of a gas, the ions, in virtue of their charge, acquire a velocity whose average value depends on the electric intensity

¹MSA. Intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

¹ Presidential address before Section A of the Australasian Association for the Advancement of Science.

and on the resistance which is offered to the movement; under the influence of the electrical forces the ions drift, as it were, in a definite direction, the positives traveling to the negative electrode, and *vice versa*, a motion in which the uncharged molecules have no part. Other things being equal, it is assumed that this drift velocity of the ions is directly proportional to the electric intensity and following the suggestion of M. Langevin, the term "mobility" has been adopted for the average velocity acquired by an ion under the influence of unit electric force. At the present time the mobility of a class of ions is its most readily determined property, and it is principally to observations of the mobility of the ions in different gases and under various conditions that we must look for a clue to the nature of the ionic structure. In all cases I shall state the value of the mobility as that of the velocity, in centimeters per second, due to an electric force represented by a potential gradient of one volt per centimeter, that is, in practical units.

Two types of ion are recognized as existing naturally in the air, the small ion, with a mobility of about one and one half under normal conditions, and another, discovered by M. Langevin,² and called by him the large ion, which is characterized by the very small mobility of only $\frac{1}{3000}$. To these I now add a third, which has a mobility of about $\frac{1}{100}$ under normal circumstances. It may be called, for the present at least, the ion of intermediate mobility, or the intermediate ion.

M. Bloch³ finds in air bubbled through water ions of mobility of the order of one or two tenths; these seem to form a fourth class of ions and it would be interesting to know if they exist in air not specially treated.

¹ Langevin, *C. R.*, t. 140, p. 232, 1905.

² Bloch, *C. R.*, t. 145, p. 54, 1907.

The small atmosphere ions are identical with those artificially produced in air by ionizing agents which have been made the subject of such numerous researches as described by Professor Bragg in his address. There is now considerable knowledge, resumed in the beautiful kinetic theory of gases, of molecular movements and dimensions, and when it is thought that an ion moves more slowly in an electric field than would a single molecule if charged, as the ion must be made of the stuff of the gas in which it is formed, what more natural than to consider it a cluster of a few molecules? This idea has been generally adopted. The small ions are thus assumed to be of somewhat greater size than their fellow molecules, but as the mobility notably increases with decrease of pressure, and with rise of temperature, their diameter is apparently not a constant quantity.

The direct argument, which is used to support this view, considers that in the numerous collisions which occur between the charged and uncharged molecules, in many cases the kinetic energy of the latter will not be great enough to carry them away, after impact, from the attraction of the charge. The charged molecule will thus collect other molecules around it, but as the effect of the charge on the outer members of the cluster diminishes as the collection of molecules increases, the growth will cease when the size is such that the attraction of the charge at the surface of the cluster, in grazing impact of ion and molecule, is just insufficient to hold the latter as a permanent member of the ionic system. The principle involved, in calculating the value of the limiting radius, is similar to that which determines whether a comet, in its close approach to the sun, shall become a permanent member of the solar system or wander into the space from which it came. The calcula-

tion of the ionic size which has been made on these lines assumes the ions as charged, the molecules as uncharged conducting spheres, and, taking the radius of the molecules, as 10^{-6} centimeters, reaches the conclusion that the radius of the ion can not exceed three times this value.

To account for the change of mobility associated with alteration of the pressure or temperature conditions, it is supposed that the clusters of molecules forming the ions consist of fewer members at low pressures and at high temperatures than under ordinary circumstances. As the temperature rises, for instance, the ion may be imagined as shedding one by one its component molecules. The mobility, however, varies continuously and not by jumps; it may, therefore, be considered, in addition, that a cluster at any temperature does not always consist of the same number of molecules. In the numerous collisions, to which an ion as a constituent of a gas is subjected, a molecule of the cluster may be lost at one, to be gained at another impact, the cluster acting on the whole as if it contained the average number of members; it is this average number which, from this point of view, must be taken as decreasing continuously with rise of temperature.

From a consideration of the slow movement of the ions in an electric field compared with that which it is assumed a single charged molecule would have in the same circumstances, it is possible, with the aid of the principles of the kinetic theory, to make an estimate of the number of molecules which go to make an ion. The argument is given in Mr. Phillips's paper on "Ionic Velocities in Air at Different Temperatures,"⁴ and he calculates from his results that the positive ion at -179° C. consists, on the average, of about four and a half molecules (4.63), while at $+138^{\circ}$

C. the average number is only about one and a half (1.52). For the negative ion slightly smaller figures are obtained.

Such an idea of the small ion, based, either on the direct argument in its restricted form already noted, or on the calculation just mentioned, can not be considered satisfactory, and it is now shown to be unnecessary by two workers at opposite sides of the world, Mr. Wellisch at Cambridge and Mr. William Sutherland at Melbourne.

In this connection it is interesting to recall another physical problem which apparently also required for its explanation a shrinkage of the molecules with rise of temperature, that of the relation between the temperature and the viscosity of a gas. The solution of the problem was finally reached in 1893 by Mr. Sutherland, from a consideration of the influence of molecular force in bringing about collisions which would otherwise not occur, the investigation being published in his paper on "The Viscosity of Gases and Molecular Force."⁵ The result of mutual attraction, only sensible at small distances, is to make the molecules, considered forceless, behave as if they had a diameter greater than the true value. As the molecular force is less effective in causing collisions the greater the velocity with which two molecules approach each other, the apparent diameter to which it gives rise is less the higher the temperature. It is now shown by the writers I have mentioned that there is a similar effect due to the ionic charge. Owing to the influence of the electrical attraction, collisions between ions and molecules take place which would otherwise be avoided, and consequently the ions act as molecules of greater than the normal size, the apparent diameter decreasing as the temperature rises.

For the movement of an ion through

⁴ Phillips, *Proc. R. S., A*, 78, p. 167, 1908.

⁵ Sutherland, *Phil. Mag.*, 36, p. 507, 1893.

a gas, M. Langevin* has given for the mobility, k , and the coefficient of diffusion, D , the equations,

$$k = \frac{eL}{MV}; \quad D = \frac{LV}{3},$$

where e denotes the ionic charge, L the mean free path of the ion, M its mass and V its mean velocity of thermal agitation. Mr. Wellisch in his investigation calculates the mean free path of the ion, taking into account the effect of the ionic charge in increasing the collision frequency, and, substituting in the above equations, reaches general expressions for the two quantities under consideration. If the mass and dimensions of the ion are taken as the same as those of the molecule the expression for the mobility becomes at 0°C .

$$k = \frac{A\eta}{\rho_1 p} \left\{ 1 + \frac{(K_1 - 1)\pi A^2 \eta^2}{2\rho_1 p_1^2} \right\}^{-1}$$

and that for the coefficient of diffusion at the same temperature

$$D = \frac{\eta}{\rho} \left\{ 1 + \frac{(K_1 - 1)\pi A^2 \eta^2}{2\rho_1 p_1^2} \right\}^{-1}$$

where A ($=1.30 \times 10^{10}$ electrostatic units) is the product of the number of molecules per cubic centimeter and the ionic charge, η the coefficient of viscosity of the gas, K its specific inductive capacity, ρ the density and p the pressure in dynes per cm^2 , the symbols with subscripts referring to values under the standard conditions as to temperature and pressure.

To test the theory Mr. Wellisch gives the following table of comparison between the observed and the calculated values, the observed mobilities, except in the case of air, hydrogen, nitrogen and oxygen, being the results of a series of determinations recently made by him.

Mr. Wellisch further shows that if d

Gas or Vapor	Formula	Molecular Mass	$\rho_1 \times 10^3$	$\eta \times 10^6$	$(K_1 - 1) \times 10^3$	k_{700}		
						Calculated	Observed	
							+	-
Air			129	177	59	1.25	1.86	1.87
Hydrogen	H_2	2	9	85	26	0.32	6.70	7.95
Carbon monoxide	CO	28	125	168	69	1.16	1.05	1.10
Nitrogen	N_2	28	125	168	69	1.31	1.6	mean
Oxygen	O_2	32	143	191	84	1.25	1.86	1.90
Carbon dioxide	CO_2	44	198	141	96	.87	.77	.81
Nitrous oxide	N_2O	44	198	141	107	.81	.79	.86
Ammonia	NH_3	17	76	90	770	.21	.70	.76
Ethyl alcohol	$\text{C}_2\text{H}_5\text{O}$	46	208	89	940	.19	.82	.96
Sulphur dioxide	SO_2	64	286	122	995	.17	.42	.39
Ethyl chloride	$\text{C}_2\text{H}_5\text{Cl}$	64.5	288	93	1,554	.11	.32	.30
Ethyl ether	$\text{C}_2\text{H}_5\text{O}$	74	330	69	742	.24	.28	.30
Carbon tetrachloride	CCl_4	153.8	686	158	426	.20	.29	.30

denote the coefficient of interdiffusion of a molecule through the gas,

$$\frac{D}{d} = \left\{ 1 + \frac{(K_1 - 1)\pi A^2 \eta^2}{2\rho_1 p_1^2} \right\}^{-1}$$

and by the following table indicates the nature of the agreement between the calculated and observed values.

Gas	$\frac{(K_1 - 1)\pi A^2 \eta^2}{2\rho_1 p_1^2}$	d Observed	D	
			Calculated	Observed ^a + -
Air	3.70	.150	.032	.028 .043
H_2	5.39	.131	.205	.123 .190
O_2	3.56	.189	.041	.025 .040
CO_2	2.52	.109	.031	.023 .028

Both in the case of the mobility and in that of the coefficient of diffusion the agreement between the calculated and the observed values is, on the whole, quite satisfactory, the conclusion being that the behavior of the ion can be explained on the supposition that it consists of a single molecule associated with a charge equal to that carried by the monovalent ion in electrolysis.

Mr. Wellisch read an account of this investigation of the mobility and diffusion of the ions before the Cambridge Philosophical Society at its meeting held on

^a See Jeans, "Dynamical Theory of Gases," p. 253.

^b Townsend, *Phil. Trans.*, A, 193, p. 129, 1900.

November 9, 1908, and communicates a paper on the same subject to this section.

Mr. Sutherland, to our regret, is unable to be present at this meeting of the association, but he allows me to communicate to the section a letter of his on the theory of the small ion written to me on February 6, 1908, and permits me to mention the results of his investigation at this stage of our proceedings.

Amplifying the discussion developed in his viscosity paper by the addition, in the energy expression, of a term representing the electrical potential energy of ion and molecule when in contact, Mr. Sutherland, in his letter, proceeds to investigate the relation between the mobility and temperature and deduces for the mobility of the ion the simple expression,

$$k = \frac{A\theta^4}{C' + \theta - \theta'}$$

where A is a constant, θ the absolute temperature, θ' the absolute boiling point, under the experimental pressure, of the substance of the gas in which the ions are formed, and C' a constant similar to that represented by C in his now well-known viscosity formula.

To test the theory Mr. Sutherland applies the equation to the experiments of Mr. Phillips⁹ on the negative ion, taking $A = 0.1764$, $C' = 150.5$ and $\theta' = 70$, with the following results:

θ	411	399	388	378	348	333	285	209	94
k calculated	2.48	2.42	2.38	2.27	2.13	2.05	1.75	1.22	.235
k observed	2.49	2.40	2.39	2.21	2.125	2.00	1.78	1.23	.235

As will be noticed, the comparison of the mobility calculated from the above expression with the results of Mr. Phillips's valuable series of observations, shows an accordance well within the limits of experimental error, over the whole range of temperature from 95 degrees to 411 degrees absolute. The apparent decrease in

the size of the ion with rise of temperature, as discovered by Mr. Phillips, is thus shown to be due to an effect of the ionic charge similar to that of molecular force which accounts for the apparent shrinkage of the molecules in the viscosity problem.

Mr. Sutherland shows, in addition, how his investigation enables an estimate to be made of the diameter of the ion, and concludes from his determination that most probably the small gaseous ion is the ordinary ion of electrolysis.

Mr. Sutherland's expression for the mobility of the ion, by containing a symbol representing the boiling point of the gas substance at the pressure of the experiment, indicates a dependence of the mobility on the pressure of the gas; the comparison of the values given by it have yet to be compared with the results of experiment.¹⁰

The idea of the small ion as a cluster of a few molecules, founded on insecure assumptions, was perhaps chiefly characterized by its numerical vagueness; its replacement by a definite theory can not but be regarded as marking a great advance in our knowledge of ionic structure.

Turning now to the consideration of the larger ions in the air, it may be said at once that our knowledge is as yet but represented by the mere collection of the results of experimental investigations. The large ions were discovered by M. Langevin¹¹ in 1905, who found that their movement, in an electric field with a potential gradient of one volt per centimeter, is only at the rate of one three-thousandth of a centimeter per second, but that, under natural conditions, their number is about fifty times as great as that of the small ions. In a later communication MM. Langevin

⁹ Langevin, *Ann. de Chimie et de Physique*, t. 28, p. 289, 1903.

¹¹ Langevin, *C. R.*, t. 140, p. 232, 1905.

¹⁰ Phillips, *loc. cit.*

and Moulin¹² describe an instrument for automatically registering the ionization of the atmosphere caused by the small and the large ions, with which they have experimented during the past few years; from the use of such an apparatus most important information will be derived.

For some time observations of these large ions, in the air at normal pressure, have been made at the physical laboratory of the University of Sydney. In this investigation I have been joined, at times, by students whose names will be given in connection with the mention of results they have obtained, and throughout have been most ably helped by my assistant, Mr. Carl Sharpe. Owing to the variable character of the natural ionization, the work has proved extremely tedious, as it is only on somewhat rare occasions that a series of observations is accordant enough to give a definite measure of the mobility. The ionization is more uniform after sunset and we observe mainly in the night time.

All our observations have been made with apparatus constructed after the pattern of that used with such success by Professor Zeleny,¹³ in his determination of the mobility of the small ions. In such an instrument a uniform stream of air flows through a metal tube which forms the outer conductor of a cylindrical condenser, the ions drifting on to an inner axial electrode, due to the forces in the electric field established between the tube and the axial rod. The theory of the method of finding the mobility with such an apparatus, as given by Professor Zeleny, is well known; it has been followed without modification in calculating the results of the present series of experiments. Greater uniformity in the ionization is obtained if the air, before reaching the measuring tube, is drawn

through a considerable length of piping. We have not noticed any effect on the nature of the ions due to the somewhat prolonged contact of the air with the metal of the pipes, and in most of our experiments several meters of iron or of galvanized iron piping have been employed. In all cases Dolezalek electrometers have been used to measure the ionization currents.

During the investigation some definite results have been obtained, of which I propose to give a general account.

In thinking of M. Langevin's discovery the idea must have occurred to many, and is indeed suggested by Professor Rutherford in his book on "Radio-active Transformations," that the large ions may be due to the presence of water vapor. My efforts to elucidate this point have resulted in finding that there is a definite relation between the mobility of the ion and the amount of moisture in the air.

When a current of air is passed over hygroscopic substances, without mechanical filtration, Mr. S. G. Lushy finds that large ions are absorbed and has noticed a loss in number amounting to 55 per cent., after the air had flowed over a tray containing phosphorus pentoxide. I find, in addition, that after leaving the drying agent, those large ions which still exist in the air decrease in mobility with time, and that when the relative humidity changes from 80 to 4 per cent., at a temperature of 19° C., they are not in equilibrium with the new vapor pressure conditions until after the lapse of about twelve minutes. Owing to the variable nature of the natural ionization, and perhaps to other causes, the calculated mobilities exhibit considerable irregularities, but show in an unmistakable manner, when the equilibrium state is established, a dependence of the mobility on the amount of water vapor in the air, the relation between the two

¹² Langevin and Moulin, *Le Radium*, 4, p. 218, June, 1907.

¹³ Zeleny, *Phil. Trans.*, A, 195, p. 193, 1900.

quantities being apparently a linear one between the limits of the absolute humidity represented by 0.5 and 19.0 (grms./ m^3), corresponding to relative humidities of 4 and 100 per cent. The mean mobilities for these values of the humidity, from results so far obtained, are 1/1280 and 1/3370, respectively. In other words the mobility for an absolute humidity of 2.4 is twice as great as that for a humidity of 15.4 (grms./ m^3). The observations are not regular enough to show if there is any difference between the mobilities of the positive and negative ions. Owing to ionization being caused by phosphorus, it is not advisable to use phosphorus pentoxide as the drying agent in such experiments, and calcium chloride has been employed in all cases.

The intermediate ion has been under observation for only a comparatively short time. The measures so far made, however, show that the mobility is largely affected by change of the humidity of the air, the magnitude varying from one fifteenth to about one tenth of that number as the absolute humidity alters from 0.5 to 15 (grms./ m^3) at a temperature of about 22° C. To this statement there is a limitation, the extent of which I do not as yet fully know—in air in its natural state with the absolute humidity between 14 and 16 grms./ m^3 , at 22° C. when the ionization due to this class of ions is relatively weak, the mobility, at least of the positive ions, is of the order of 1/65, while with strong ionization the value is only about half as great. Unless the limitation just mentioned provides an exception, on further investigation, no definite difference between the mobilities of the positive and negative ions of this class can be deduced from the observations.

The facts just described prove that there is a definite connection between the ions and the water vapor of the air, and open

up an interesting field for speculation as to the development and structure of electrified clusters, and as to the nature of the resistance which they experience in drifting through the crowd of molecules. The basis of the structure is, of course, the molecular ion, which, it is well known, originates from effects associated with radio-active transformations occurring in the air, the ionization being primarily due to the presence of radium and thorium in the material of the earth's surface. The growth to more complex structure apparently occurs by the collection of water molecules round the molecular ion, owing to the influence of its charge.

Seemingly from a consideration of the experimental results, we must recognize at least two forms of electrified molecular aggregation in the air which are stable under ordinary conditions. As the mobilities depend on the humidity, it might not unreasonably be supposed that the intermediate and large ions represent stages in the development of the small ions into visible drops of water, which occurs if the air becomes sufficiently supersaturated. It seems, therefore, curious that the large ions are not separately apparent as condensation nuclei in cloud experiments.

Mr. C. T. R. Wilson¹⁴ has shown that in such experiments the presence of a moderate electrical field prevents the formation of drops if the expansion ratio does not exceed the value 1.27. This proves that the nuclei for these small expansions are ions which can be removed by the field before the expansion takes place. I have carefully repeated the observations, with an apparatus similar to that described by Mr. Wilson, in order to determine if the effect of the electric field varies with the time it is on before expansion, and find the full effect whether the interval is one second or twenty minutes. With the fields

¹⁴ Wilson, *Phil. Mag.*, June, 1904.

used it takes several minutes to remove all the large ions, on account of their small mobility, whereas the small ions disappear in less than a second, so the nuclei for the drops formed with expansions below 1.27 are small, not large ions. To test whether the large ions become visible at a lower humidity than that at which the small ones appear, Mr. E. P. Norman, at the Sydney University Laboratory, has repeated Mr. Wilson's experiments on the supersaturation required for condensation,¹⁸ with natural air over mercury. Commencing with a humidity between 60 and 70 per cent., after removing the "dust," no condensation occurs, not only below saturation, but not until the supersaturation becomes four-fold, as in the earlier experiments over water. In all our experiments the observations have been repeated with air which has remained undisturbed in the apparatus overnight, in order that time might be available for the reproduction of the large ions if they had been initially withdrawn, but the results of the first expansion in the mornings appeared in no case different from those of the later ones. Now Mr. Lusby finds, using two Zeleny tubes in series, joined by earthed piping whose length can be varied, that if all the large ions are removed from a stream of air by the first tube, they are fully reproduced in number in about 22 minutes. Our failure to detect the large ions is not, therefore, because they were removed with the "dust," unless, indeed, large ions are not produced in closed vessels, a matter which it would be difficult to determine.

Considering that in natural air the large ions are fifty times more numerous than the small ones, it is hard to reconcile the fact that the separate existence of the former has never been suspected in condensation experiments with the idea of the

large ion as representing a stage in the growth of the small one to a condition of visibility, and the experimental evidence as to the position of the large ion in this connection seems as yet in an unsatisfactory state.

MM. Langevin and Moulin¹⁹ describe the small and the large ions as playing different parts in the formation of natural clouds, but the statement is merely one of suggestion.

As all the ions have the same charge, the electrical state of the atmosphere is conditioned by the numbers of the ions of each class which exist at the time. Should the numbers of positives and negatives be equal the air is electrically neutral, if, however, one kind greatly outnumbers the other the air is thereby highly electrified.

The number per cubic centimeter, or the specific number, as it may be called, of each class of ions in the air is an extremely variable quantity, particularly in the day time. From measurements in other parts of the world it is considered that the specific number of the small ions varies between 500 and several thousands. Between this estimate and that given by my own experience there is an amazing discrepancy. In a series of 128 observations, taken at Sydney in the early part of the year 1907, the maximum specific number is 157, the minimum zero, the mean number for the positives being 39 and that for the negatives 38. The European determinations are based on observations taken with Dr. Ebert's well-known ion counter, the principle of the apparatus being that of the Zeleny tube. With our present knowledge of the existence of the intermediate ions, it can readily be shown that the inner electrode of the instrument is altogether too long. The apparatus, as ordinarily employed, catches not only the small ions, but a proportion of the others as

¹⁸ Wilson, *Phil. Trans.*, A, 189, p. 265, 1897.

¹⁹ Langevin and Moulin, *loc. cit.*

well. Calculating with my own measures of the mobilities and specific numbers, it appears that the determination of the specific number of the small ions from the indications of the Ebert instrument must be from two to four times too great. As for the remaining part of the discrepancy, having used Dolezalek electrometers in my own observations, I may, perhaps, be prejudiced in thinking that the metal leaf electroscope of the Elbert apparatus is an unreliable appliance for use in such determinations; in any case the matter must be made the subject of a special enquiry, but in the meantime I have the utmost confidence in my own measures.

With regard to the other ions, from the very limited series of observations which I have as yet made of the intermediate ones, in air in its natural state, what I have previously called relatively strong ionization is represented by about one thousand per cubic centimeter, while for the relatively weak ionization the number is about two hundred.

For the specific number of the large ions, a series of 117 observations gives 5,500 as the maximum and 600 as the minimum, the mean for the positives being 1,914 and for the negatives, 2,228.

The numbers given, with the exception of those for the intermediate ion, are the results of measures with air drawn directly into the testing apparatus without the intervention of any pipes; later observations give much higher values for the specific number of the large ions in air led through a considerable length of piping.

It is now well known, since Lord Kelvin's memorable work on the subject, that a potential difference exists between the earth's surface and the upper layers of the atmosphere. In the electrical field, which is thus indicated, the ions in the air move more or less steadily in a vertical direction,

the negatives ordinarily traveling upwards, the positives downwards to the earth. Such a movement constitutes a vertical electric current in the air, the magnitude at any time depending on the air's specific conductivity and the value of the potential gradient at the moment. The specific conductivity is represented by the sum of the continued product of the specific number, the mobility, and the charge for each class of ion. An instrument designed by Dr. Gerdien, in which an electroscope is used as in the Ebert apparatus, has been universally employed for such determinations as have been made of this important quantity. It measures the sum of the conductivities due to each type of ionization, and the calculation of the result from observations with the apparatus is not affected by the discovery of a new class of ions. The complexity of the natural ionization, however, prevents the instrument being used to accurately determine the specific number of the small ions. The average value of the specific conductivity of the air in other parts of the world, as given by the Gerdien apparatus, is about 10^{-4} in electrostatic units.¹⁷ The magnitude of this quantity can be calculated from the measures of the mobilities and specific numbers of the ions, and the average specific conductivity of the air at Sydney, so determined, is only about one tenth of the value just stated. Here again there is a considerable discrepancy between my own and other measures which has yet to be investigated.

With increasing knowledge we can look forward to developments of importance to meteorology in connection with ionic observations; just now it is doubtful, I think, if valuable effort is not being wasted as a result of over-confidence in the present state of the art.

¹⁷ Gerdien, *Gesell. Wiss. Gottingen, Nachr., Math-Phys. Klasse*, 1, p. 77, 1907. Dike, *Terr. Magn. and Atmos. Elect.*, September, 1908.

Such is a sketch of our present knowledge of the ions of the atmosphere. With the publication of Mr. Wellisch's and Mr. Sutherland's investigations we have reached a definite idea of the small ion in air—a molecule, which, as the attraction of its charge brings about collisions which would otherwise not occur, acts as if it were one of more than the normal size—the conception enabling our experience to be not only simply but exactly described. Of the large ions, no such definite picture can as yet be drawn. Ions similar in character have been observed in gases from flames and in other cases, and it is to be hoped that the material which is now being collected may soon prove sufficient, in the hands of those specially skilled in the methods of the kinetic theory of gases, for a discussion of the life history of these molecular clusters. The study of the natural ions has a special interest, as a wider determination of the facts of the ionization of the air means an advance towards a more comprehensive knowledge of atmospheric electricity. J. A. POLLOCK

UNIVERSITY OF SYDNEY

THE ELIZABETH THOMPSON SCIENCE FUND

THE thirty-fourth meeting of the board of trustees was held at Harvard College Observatory, Cambridge, Mass., on April 29, 1909. The following officers were elected:

President—Edward C. Pickering.

Treasurer—Charles S. Rackemann.

Secretary—Charles S. Minot.

It was voted to close the records of the following grants, the work having been completed and publications made: No. 115 to H. S. Carhart, and No. 128 to L. J. Henderson; and to close upon receipt of publications the accounts of the following grants: No. 96, H. E. Crampton; No. 108, E. Anding; No. 112, W. J. Moenkhaus; No. 126, L. Cuénot; and No. 132, W. G. Cady.

Reports of progress were received from the following holders of grants:

No.	No.
98. J. Weinzirl.	137. C. H. Eigenmann.
111. R. Hürthle.	138. Mme. P. Šafarik.
117. E. Salkowski and C. Neuberg.	139. J. Koenigsberger.
119. J. P. McMurrich.	140. K. E. Guthe.
123. E. C. Jeffrey.	141. J. T. Patterson.
131. F. W. Thyng.	142. W. J. Hale.
133. J. F. Shepard.	143. R. W. Wood.
135. A. Negri.	144. G. A. Hulett.
136. H. A. Kip.	145. J. de Kowalski.
	146. M. Nussbaum.

The secretary stated that during the past year no reports had been received from the following holders of grants:

22, 27. E. Hartwig.	121. A. Debierne.
109. A. Nicolas.	124. P. Bachmetjew.

It was voted to make the following new grants:

- No. 147. \$200 to Professor Johannes Müller, Mecklenburg, Germany, to investigate the physiological chemistry of inosit.
- No. 148. \$200 to Professor C. C. Nutting, Iowa City, Iowa, for a report on the Gorgonacea of the Siboya Expedition.
- No. 149. \$200 to Professor Ph. A. Guye, Geneva, Switzerland, for determinations of atomic weights.
- No. 150. \$100 to Professor Charles A. Kofoid, Berkeley, Cal., for an investigation of the life history of the Dinoflagellates.
- No. 151. \$150 to Professor Otto v. Fürth, Wien, Austria, for a research concerning the relation of the internal secretion of the pancreas to the general metabolism and especially to the combustion of carbohydrates.
- No. 152. \$150 to W. D. Hoyt, Esq., Baltimore, Md., to study the fruiting of the marine alga, *Dictyota dichotoma*.
- No. 153. \$250 to W. Doberck, Esq., Sutton, England, for a position micrometer to be used in astronomical observations.
- No. 154. \$100 to Dr. J. P. Munson, Ellensburg, Washington, for an investigation of the minute structure of the chelonian brain.

CHARLES S. MINOT,
Secretary

THE RETIREMENT OF PRESIDENT ELIOT

THE faculty of arts and sciences of Harvard University has passed a minute on the services of President Eliot which reads as follows:

The faculty of arts and sciences records with gratitude its sense of the services which Charles William Eliot has rendered to Harvard University and to its own members. The changes he has wrought in the university will be remembered so long as the university endures. To this faculty he has been a guide and a friend no less than a leader. The qualities which mark him as great have nowhere appeared more clearly and spontaneously than in its meetings. He has shown judgment and resource, devotion to progress, love of truth, contempt for sham and indirection, and patience with those who differed or opposed. He has welcomed in catholic spirit every variety of intellectual ability, and has furthered the extension of every field of knowledge. He has been frank in the admission of evils, courageous and skillful in seeking for remedies; unflinchingly attentive to every detail, always mindful of the large question of policy; cogent and effective in debate, generous toward the arguments of others. In the university and in this faculty, as in the outer world, he has stood for freedom of opinion and expression. He has been a leader not through official position but by force of character and intellect. His dealings with the teaching staff have been open, equitable and liberal to the extent of every available resource. His close contact with the members of the faculty has deepened in their hearts, with every added year of his long term, confidence, admiration and warm regard; and they now part from him with reluctance, but with thankfulness for what has been achieved by him and under him, and with faith that his work will be maintained.

THE WINNIPEG MEETING OF THE BRITISH ASSOCIATION

THE local secretaries for the meeting of the British Association for the Advancement of Science beg to remind intending visitors from the United States that members of the American Association for the Advancement of Science will be admitted as full members of the British Association for the Winnipeg meeting (and entitled to receive the volume of proceedings), on payment of a fee of \$5. The meeting will be held from the twenty-fifth of August to the first of September, inclusive, and it is anticipated that a large number of visitors from the United States, as well as from Canada and Europe, will attend. It is important

that those intending to be present should send in their names to the local secretaries, University of Manitoba, Winnipeg, as soon as possible; printed matter bearing on the meeting will gladly be furnished, as well as postcard forms giving various details of use to the local committee. The secretaries are in communication with the various passenger associations in connection with reduced fares via the United States, but for the present no definite statement can be given, except that the special fares in force in connection with the exposition at Seattle may be taken advantage of. A concession of single fare for the return journey has been secured on all Canadian railways, and those entering Canada should be able to obtain from the agent at the port of entry the standard convention certificate enabling them to secure this privilege. Circulars of information upon this and other matters will be forwarded upon application to the local secretaries.

SCIENTIFIC NOTES AND NEWS

DR. IRA REMSEN, president of the Johns Hopkins University, has been elected president of the Society for Chemical Industry for the meeting to be held next year in Glasgow.

MR. LAZARUS FLETCHER, F.R.S., the keeper of the department of mineralogy since 1880, has been appointed to the post of director of the natural history departments of the British Museum, vacant since the retirement of Dr. E. Ray Lankester.

AMONG the honorary degrees awarded by Columbia University at its recent commencement was that of master of science on Mr. B. B. Lawrence, the mining engineer; a doctorate of science on Dr. S. F. Emmons, of the U. S. Geological Survey; a doctorate of letters on Dr. Mary Whiton Calkins, professor of philosophy and psychology at Wellesley College, and a doctorate of laws on Dr. A. Lawrence Lowell, president of Harvard University.

NEW YORK UNIVERSITY has conferred its doctorate of laws on Dr. Borden P. Bowne, professor of philosophy in Boston University.

DR. S. O. MAST, associate in biology at the Woman's College of Baltimore, has received

the Cartwright prize of \$500 for his work on "The Effect of Light on the Movements of Lower Organisms," awarded by the College of Physicians and Surgeons, Columbia University.

THE Linnean Society has presented its gold medal to Dr. F. O. BOWER, F.R.S., regius professor of botany in the University of Glasgow.

PROFESSOR W. F. OSGOOD, of Harvard University, has been elected corresponding member of the Mathematical Society of Charkow.

M. E. BOUDIER has been elected a corresponding member in the Paris Academy of Sciences in the section of botany.

DR. GEORGES DREYER, professor of pathology in the University of Oxford, has been elected a member of the Danish Royal Academy of Letters and Science.

DR. W. W. DANIEL, professor of chemistry at the University of Wisconsin, has retired from the chair which he has held since 1868. His former students have presented the university with a portrait by Mr. J. C. Johansen, of New York. *

THE trustees of Columbia University have awarded the Ernest Kempton Adams research fellowship, for the year 1909-10, to Professor C. W. Chamberlain, of Vassar College.

At a meeting of the board of directors of the Rockefeller Institute for Medical Research, held on May 29, the following promotions and appointments were made: Associate, Paul A. Lewis (pathology); Assistant, F. Peyton Rous (pathology); Scholar, Angelia M. Courtney (chemistry).

DR. C. D. PERRINE, of the Lick Observatory, has proceeded to Buenos Ayres to assume the directorship of the Argentine National Observatory at Cordoba, vacant by the death of Dr. Thome. His address will be Observatorio Nacional, Cordoba, Argentina.

THE secretary of the Smithsonian Institution and Mrs. Charles D. Walcott sailed on June 5 to attend the commemoration of the centenary of the birth of Charles Darwin as the representative of the institution. During his stay in Great Britain, Dr. Walcott will visit the northwest coast of Scotland to collect and study specimens of Cambrian fossils found

in that locality. He will return to Washington on July 3, after which he will proceed to British Columbia to continue there his field work.

PROFESSOR L. H. BAILEY, director of the College of Agriculture, Cornell University, has leave of absence for next year. Professor Herbert J. Webber will act as director.

DR. A. M. TOZZER, of Harvard University, has been given leave of absence for 1909-10 to carry on archeological investigations in Guatemala.

DR. NETTIE M. STEVENS, associate in experimental morphology at Bryn Mawr College, who has been studying at the Zoological Station in Naples and the University of Würzburg as the Alice Freeman Palmer research fellow for the year 1908-9, will resume her work at the college next year.

DR. PAUL C. FREER, director of the Bureau of Science, Manila, has left, in April, for Europe by the Trans-Siberian route. Dr. Freer will spend some time studying the laboratory methods of the leading scientific institutions of Europe. He will return to the Orient after two months in this country.

DR. CHARLES L. EDWARDS, professor of natural history at Trinity College, will spend next year in Europe.

DR. F. O. GROVER, professor of botany at Oberlin College, will spend next year abroad.

LIEUTENANT SHACKLETON is expected to reach England about the middle of June. Several members of the *Nimrod* expedition have reached England, including Mr. Raymond E. Priestley, of Bristol, the geologist; Mr. G. E. Marston, of London, the artist; Mr. Ernest Joyce, London, who was in charge of the supporting party; Mr. Frank Wild, of Bedfordshire, who accompanied Lieutenant Shackleton furthest south, and Mr. Bernard Day, of Leicester, who had charge of the motor car.

DR. HENRY P. WALCOTT, chairman of the Massachusetts State Board of Health, will preside at the International Congress of Hygiene and Demography, which it is proposed to hold in Washington next year.

DR. W. H. HOWELL, dean of the Johns Hopkins Medical School, will give the anniversary

address at the Yale Medical School, his subject being "The Medical School as Part of the University."

DR. CHARLES S. MINOT, of the Harvard Medical School, delivered on May 27, at St. Louis, the commencement address in medicine for Washington University. The address was entitled "On Certain Ideals of Medical Education," and will be published shortly.

DR. DICKINSON S. MILLER, professor of philosophy at Columbia University, will give the Phi Beta Kappa address at Hobart College.

PROFESSOR I. WOODBRIDGE RILEY, of Vassar College, delivered the annual address before the American Medico-Psychological Association at Atlantic City on June 2. The subject was "Mental Healings in America."

The Electrical World states that an unfortunate complication has arisen concerning the location of the memorial statue to Lord Kelvin in his native city of Belfast. It has been decided to erect the statue in the grounds of the Queen's College, but it was subsequently pointed out that such use of the grounds would be legally a breach of trust under the terms of tenure of the property. In the meantime, some of the subscribers to the memorial have served formal notice restraining the Lord Mayor from expending any of the money subscribed until the questions regarding the site have been satisfactorily determined.

DR. WILHELM ENGELMANN, professor of physiology at Berlin, has died at the age of sixty-five years.

DR. GEORGE VON NEUMAYER, the eminent meteorologist, has died at Neustadt at the age of eighty-three years.

TABLES at the laboratory of the United States Bureau of Fisheries, at Beaufort, North Carolina, will be available for the use of investigators after July 1. Requests for further information should be addressed either to the commissioner of fisheries, Washington, D. C., or to the director of the laboratory, Beaufort, N. C.

THE third annual geographical conference was held, on the invitation of Professor Davis, in the Geographical Laboratory of Harvard University on Saturday, May 29, and was at-

tended by over forty teachers from the schools of Boston and neighboring cities. Recent proposals regarding the teaching of geography in secondary schools were discussed, and an excursion to the coastal plain of Maine was planned for June 26.

At the last meeting of the International Physiological Congress, which was held at Heidelberg, in 1907, it was decided to hold the next Congress at Vienna in 1910, at Whitsuntide. The *British Medical Journal* states that it has been found that at this time of the year it would be impossible for a large number of physiologists to attend the congress, and the local committee of the congress at Vienna has therefore, after consulting the local secretaries in the various countries, determined to change the date of the congress. In accordance with the general wish, it will be held from September 26 to 30, 1910.

It has been arranged to transfer the whole of the Vatican Observatory to the summit of the Vatican Hill, 100 meters above the square of St. Peter's, where a section of the observatory has been for some years.

FOREIGN papers state that the central committee of the Austrian Alpine Club has by the authorities of Munich been put in possession of a large building with excellent accommodation and well situated on the banks of the Isar. The club proposes to inaugurate an Alpine museum in its new building.

THE Pacific coast will soon be the scene of an interesting tree-growing experiment. The United States Forest Service is planning to introduce a number of the more important eastern hardwoods into California, and will this year experiment with chestnut, hickory, basswood, red oak and yellow poplar or tulip trees. Small patches of these trees will be planted near the forest rangers' cabins on the national forests, and if these do well larger plantations on a commercial scale will soon be established on wider areas. There are over 125 different species of trees in California, a number of which produce some of the most valuable varieties of lumber in the country. Although considerably over one half of the species are hardwood or broad-leaved trees, yet, with the exception of the exotic eucalyptus,

there is not a single species of hardwood here ranking in commercial importance with the leading eastern hardwoods. Climatic conditions in many parts of California are favorable for the growth of a number of the valuable hardwoods, and the absence of these trees is due mostly to unfavorable factors of seed distribution.

UNIVERSITY AND EDUCATIONAL NEWS

THE General Education Board has offered to give the Johns Hopkins University \$200,000 on condition that a million dollars be raised for the removal of the university to its new site at Homewood.

MR. N. W. HARRIS has promised to give Northwestern University \$155,000 if the college will procure the remainder of a million dollars during the coming year.

THE New York *Evening Post* states that Mrs. D. G. Richardson, who in the past has contributed liberally to the medical school of Tulane University, has recently given property valued at \$55,000, and yielding an income of \$3,000 for the endowment of the chair of botany. Professor R. S. Cocks fills the newly created chair.

THE debt of Columbia University contracted in part payment of its new site and buildings has been funded, and the United States Trust Company has taken a mortgage of \$3,000,000 on the blocks owned by the university on Fifth Avenue between forty-ninth and fifty-first streets. The university will pay off this debt in thirty annual installments.

PROFESSOR IRVING HARDESTY, the head of the department of anatomy at the University of California, has been appointed to the head of the department of anatomy in Tulane University, Louisiana.

DR. GEORGE H. LING, adjunct professor of mathematics at Columbia, has accepted the professorship of mathematics in the newly-established University of Saskatchewan.

DR. FRANK G. SPECK, instructor in anthropology, has accepted the position of assistant professor of anthropology in the University of California.

WALTER K. VAN HAAGEN, assistant in chemistry at Lehigh University, has been

elected associate professor of chemistry at the University of Georgia.

PROFESSOR J. A. BROWN has resigned his position at Dartmouth College to accept the chair of physics at the Protestant College of Beirut, Syria.

MR. CHARLES B. GATER, assistant in chemistry at the University of Wisconsin, has been chosen instructor in chemistry at the Michigan College of Mines.

PROFESSOR G. ELLIOT SMITH, F.R.S., of the Government School of Medicine, Cairo, has been appointed to the chair of anatomy in the University of Manchester.

DISCUSSION AND CORRESPONDENCE

ON THE TEACHING OF THE ELEMENTS OF EMBRYOLOGY

IN 1893 Professor A. Milnes Marshall wrote in the preface to his "Vertebrate Embryology":

Great attention has of recent years been given to the study of embryology, and yet it is curiously difficult to find straightforward accounts of the development even of the commonest animals. . . . In works professing to deal with human embryology it is more common than not to find that the descriptions, and the figures given in illustration of them, are really taken, not from human embryos at all, but from rabbits, pigs, chickens or even dogfish.

This latter practise is a most unfortunate one, and has been the cause of much confusion. The student is led to suppose that our knowledge is more complete than is really the case, while at the same time he finds the greatest difficulty in obtaining definite information on any particular point in which he is interested.

This very temperate statement needs to be repeated to-day with greater emphasis, for the attention given to the study of embryology has increased with the years; it is required from practically every student of medicine and of biology, and it is as difficult as ever, if not more so (for old accounts grow out of date), to find straightforward accounts of the development even of the commonest animals. Now, as then, our text-books leap from fish to man, back to *Amphioxus*, and forward again, with stops at intermediate stations, amphibians, reptiles and birds, in such a way as to

confuse the student seriously. His confusion is increased if he compares different books, for they are apt to select different illustrations from the unlimited body of facts; and statements are often contradictory. Moreover, it is frequently impossible to say when the description passes from one form to another, or indeed, what species of animal, or pale phantom of the imagination, is in the author's mind at all.

The distinction between fact and theory is a useful one, even in embryology; indeed, I know of no distinction so important for the student to master. But in the text-books of embryology there is a nebulous zone between peopled with morulae, blastulae, gastrulae, germ-layers, etc., which dissolve and reappear in strange forms never the same. And the student is often uncertain whether he is on the sure ground of fact, in the fascinating field of theory or in the twilight zone between. Such uncertainty is demoralizing, because it limits his respect for exact facts and does not increase his capacity for sound generalization. The student who gains his conception of a developmental sequence by combining the morula of a mammal, the blastula of a starfish, the gastrula of *Amphioxus* and the germ-layers of a frog is as far removed from connected facts as from sound theory.

Such method of the text-book is of course ill-adapted to laboratory practise and there is usually a gap between. The student's laboratory practise is usually limited to an anatomical study of a few stages of one or a few forms, and if he turns to the text-book to bind his observations into a sequence, he finds brief superficial descriptions of disconnected stages of a great variety of forms, for the most part, of course, different from those he is studying in the laboratory. Neither in his laboratory practise nor in his text-book does the student obtain genuine understanding of the development of any single form. It would be just as reasonable to expect proper comprehension of the principles of comparative anatomy of vertebrates without knowledge of the anatomy of any definite species as to expect real understanding of the principles of comparative em-

bryology from a student who does not know a single life history thoroughly.

These conditions are seriously aggravated by secondary considerations of the text-books, such as the alleged greater significance of certain aspects of the life history for various practical disciplines, which leads to unjust emphasis, and to the view that embryology is a field from which only facts of practical value are to be culled; I am far from denying the significance of the study of embryology for medicine, for instance, but I would maintain that much of its significance is lost by piecemeal selections. If the facts and principles are understood, the applications may be readily made at the proper time and place, but if they are not understood the applications are surely of doubtful value.

Theory changes so rapidly in embryology that text-books soon grow out of date; and tastes differ so widely that the selection of facts for a book fails to satisfy more than a limited number of teachers. Hence the constant procession of text-books of embryology. In this state of affairs there is bound to be a reaction, and it appears to me that this must take the form of a series of text-books dealing with the concrete development of single forms.

Probably no text-book of embryology has been so influential and of so long continued service as Foster and Balfour's "Elements of Embryology," of which the first edition was put forth in 1873, and the second edition (enlarged) in 1883, soon after Balfour's untimely death. Even now, although it has not been revised for twenty-six years, it is still in active service. The reason for this lies partly in the simplicity and clearness of the style, but largely in the fact that the greater part is a literal account of the development of a single form, the chick; it takes up the events of the development of each day, to the end of the sixth day at least, "as though the development were done by day labor," which is indeed the case, and the student obtains some idea of time-relations which are of the essence of embryonic development; he is made to see development as a continuous process marching steadily forward to a definite consummation;

and he controls the statements of the book by his observations in the laboratory; and where the latter are incomplete they can be supplemented by reference to the former.

The continued usefulness of this little book is an object lesson in embryological pedagogy by which the writer tried to profit in writing a new "Development of the Chick" which should bring the subject matter up to date, and serve as an introduction to embryology. On the whole it seems improbable that the chick will be displaced as the favorite subject for laboratory practice in embryology, because the material is of universal occurrence and available at all seasons of the year without great expense. Moreover, the technique is as simple as that of any other form, at least after the egg is laid; and the knowledge of its development, while yet incomplete, is certainly more considerable than that of any other animal with the possible exception of man himself.

Professor Metcalf's objections to the use of the chick for introducing students to the subject of embryology¹ do not appear to me to be well grounded. He complains that the embryo chick is "highly specialized" and "distorted from the general vertebrate type," and that "the space relations of the organs are distorted by secondary influences." For these reasons he prefers the frog, and wishes that there were an embryology of this form. I echo this wish and hope that Professor Metcalf will undertake to write one. I am afraid, however, that the inconsiderate agriculturalists who domesticated the hen and taught her to lay the year around have conferred on her an unfair advantage; and it appears to me better for the elementary student to study living hens' eggs than preserved frogs' eggs. This is indeed the main advantage that I see on the side of the chick. But I believe that the objections on account of "specialization" and "distortion" are more deeply rooted in tradition than in nature.

But whether the student uses the frog or the chick, or some other form, he needs a

fairly complete and modern book of reference of the same form, if not to replace, at least to supplement, the comparative text-books. In this contention I think Professor Metcalf will agree. We need above all objectivity in the teaching of embryology; we must require some basis of exact facts to support generalizations, and keep the distinction between the two clear in the student's mind.

FRANK R. LILLIE

UNIVERSITY OF CHICAGO

GENERA WITHOUT SPECIES

IN SCIENCE for February 26, 1909 (pp. 339, 340), Professor Cockerell discussed the "controversy" concerning "genera without species," pointing out the difficulty of dealing with such cases, since they are not distinctly provided for in the International Code of Zoological Nomenclature. Apparently each case should be dealt with solely on its merits. A few illustrations may help to make this point clear. In 1799 Lacépède proposed the genus *Picoides*, giving a short diagnosis of it, but omitting to refer to it any species. The diagnosis clearly indicates a woodpecker having only three toes. The only species of woodpecker at that time known with only three toes was the three-toed woodpecker of northern Europe, *Picus tridactylus* Linn. This species being clearly the basis of the diagnosis, it may be taken as the type of the genus *Picoides*, now, for a long time, current for the group containing this and other closely allied species.

In the same way, and at the same date, Lacépède proposed the name *Astur* for a genus of short-winged, long-legged hawks, giving for the genus a wholly inadequate diagnosis, without mentioning under it any species. In 1806 Froriep published a German translation ("Analytische Zoologie") of Duméril's "Zoologie analytique," adding to it, *passim*, much new matter, including the mention of examples under Duméril's genera, which, for the most part, were originally proposed by earlier authors, without, of course, the designation of types. As an example of *Astur* Froriep gave the species *Falco palumbarius* Linn., which thus may be taken as the type of *Astur*. But the genus should date

¹ SCIENCE, N. S., XXIX., May 7, 1909, pp. 738-739.

from Lacépède, 1799, and the type from Frorisp, 1806. The genus has been current for more than a century, during which period the same species has been repeatedly and independently designated as its type by various subsequent authors.

Forster in 1788 published a work ("Enchirid. Hist. Nat.") in which he gave diagnoses of the genera of birds (and other animals) then known to him, but without referring to them any species. Some of them were for the first time characterized and named, among them the genus *Gavia*. His diagnosis, with the context, shows unequivocally that *Gavia* was proposed for the loons, a group comprising, as now known, some half-dozen species, all strictly congeneric, and so different from all other birds as to constitute a distinct superfamily. *Gavia* was, furthermore, the first generic name proposed for the group. It only remained for some one later to select some one of the loon species as its type.

Muscivora was proposed by Lacépède in 1799, for a genus of tyrant flycatchers, but he referred to it no species. It was not satisfactorily determinable till a species was referred to it by G. Fischer in 1813.

Cuvier in 1800 published ("Leç. d'Anat. comp.," tab. ii.) a considerable number of genera now currently accepted from this source, without giving either diagnoses or other basis for them beyond citing their equivalent vernacular French names, which names are, however, identifiable from a slightly earlier work ("Tabl. élém. de l'Hist. nat.," 1798) of the same author where these vernacular names are coupled with their proper technical designations. In a few cases his generic names are not thus identifiable, and are hence to be ignored.

These examples, selected from many that are available,¹ seem to show clearly that "genera without species" should be dealt with

¹ For example, Lacépède, in his "Tableau . . . des Oiseaux" (1799), recognized 130 genera of birds, of which 19 were here first proposed, all solely on the basis of diagnoses; of these 11, or more than one half, are now, and always have been, in universal use; the others were homonyms or preoccupied names.

according to their individual merits. They seem also to fully answer Professor Cockerell's question, "Who can define a genus except as including species?"

It may be noted further that while this question is not considered in the International Code, it is fully discussed and provided for in the A. O. U. Code, where a diagnosis is recognized as a valid basis for a generic name, with the provision, however, that "a name resting solely on an inadequate diagnosis is to be rejected, on the ground that it is indeterminate and therefore not properly defined." This ruling is based on general usage for nearly a century, as well as on common sense; to reject it would result in the overthrow of many generic names that have been current in vertebrate zoology for almost a century. It may be added that while the A. O. U. Code of Nomenclature and the International Code of Nomenclature are in perfect accord in respect to principles and spirit, the A. O. U. Code is much fuller and more explicit than the International, taking up in detail a large number of questions not included in the latter. This may well be the case, inasmuch as the A. O. U. Code is a document of some fifty pages while the International Code is comprised in a dozen pages.

Postscript.—Since the above was sent to SCIENCE, Professor Cockerell has returned to the subject of "Genera without Species," giving abstracts of replies received by him from a number of correspondents in response to a suggestion to that effect made in his former communication.² These replies are not only interesting, but possess some importance as showing the opinions on this question of a number of entomologists and botanists. The twelve gentlemen here represented seem to pretty unanimously agree with Professor Cockerell that (to quote from one of them) "generic names published without any mention of included species are to be regarded as invalid"; or, as otherwise stated, "are nomina nuda." This remarkable unanimity seems to me to be due either to limited experience in this difficult field, or to a lack of knowledge of

² SCIENCE, May 21, 1909, pp. 813, 814.

³ SCIENCE, February 26, 1909, p. 340.

the history of nomenclature; in other words, as off-hand opinions as to what seemingly ought to be, regardless of the actualities of the case.

Nomenclature (both zoological and botanical) has attained its present stage of comparative orderliness by slow stages of development. For the first seventy years of its history such a concept as a "genotype" appears to have been rarely, if ever, thought of; and it was not until the first quarter of the nineteenth century had passed that types of genera began to be considered as a necessary part of the proper basis of a genus. Prior to 1810 hundreds of genera now in current use were proposed solely on the basis of a diagnosis; although they were accepted and have been in use from the date of their proposal, many of them were without designated types for half a century. Yet the authors of this early period were in substantial agreement as to what groups of species these generic names were intended to include. From the modern viewpoint these genera were (usually) heterogeneous groups, each comprising several modern genera. In the process of division a type was sooner or later, by restriction or by actual designation, assigned to the original genus. Not till then did the genus, from the modern viewpoint, become properly established. Many other genera of this early period, similarly proposed, are unidentifiable. I can not agree that these two categories should have the same treatment. Nor can I agree that a long-accepted genus must date from the author who, long after it was originally founded, "validated" it by designating a type for it; but rather, as indicated in the first part of this communication, that the genus should date from its founder. Otherwise nearly all of the early genera for birds would date from about 1840, after many of them had been in general use for one half to three fourths of a century. In the case of mammals, many of the early genera were not thus "validated" till many years later than those of birds. To take genera from the date of "validation" would obviously establish a new source of trouble in relation to priority of names.

It is now the custom of a large number of nomenclators to make a distinction between a

nomen nudum and a name that is for any reason unidentifiable; the former can be employed by a later author, from whom it must date; the latter can not be again used, the attempt at a diagnosis, however brief or inadequate, precluding its subsequent employment. Hence a name founded on a diagnosis, and subsequently validated, can not be taken from the validating author, but must date from the founder, if this rule be followed. Furthermore, to call a genus a nomen nudum when based on a diagnosis is a misuse of language, and entirely contrary to usage.

J. A. ALLEN

AMERICAN MUSEUM OF NATURAL HISTORY,
NEW YORK

THE ORIGIN OF THE MOON

In his inaugural lecture delivered in Columbia University, November 3, 1908,¹ Dr. Albrecht F. K. Penck, the Kaiser Wilhelm "Umtausch" Professor, spoke in part as follows concerning the geographical and geological similarities between the eastern coast of North America and the western coast of Europe:

These similarities between Europe and peninsular North America are not merely superficial ones. In a very remarkable way, these two sides of the Atlantic repeat the same structural features; there is an astonishing symmetry, as Eduard Suess has shown so clearly. The north-east of Canada and Labrador on one side, and Scandinavia with Finland, the region of Fennoscandia, on the other, are both composed of the oldest rocks we know of. These have a very complicated structure, being intruded with many eruptive rocks, and in a secondary way only, the surface features of the above regions are dependent on their structure. Both regions had already been leveled down before Cambrian times, and they sink gently down under a cover of horizontal Paleozoic strata. Both were called by Suess shields. The resemblance between these shields is the more conspicuous because both were covered during the last ice age by a glaciation which molded their surface in a similar way. In Sweden and Finland we find the same rounded

¹ See Revised A. O. U. Code, Canon XXXIV., and the explanatory "remarks."

² For the whole lecture see *SCIENCE*, February 26, 1909.

glaciated surface, the same numerous lakes, as in Canada, both regions of the earth claiming to be the land of the many thousand lakes. At the border of both regions the horizontal Paleozoic strata begin with an escarpment which is pronouncedly developed south of Lake Erie and south of the Gulf of Finland, called here the "gliut," and we shall keep this expression to designate similar escarpments. These strata continue far into the interior of Eurasia, and they do the same in North America.

And again:

It is very interesting to see how the Appalachian region ends at Newfoundland, forming the projecting eastern corner of North America, and just opposite in south Ireland, in south Wales, in Cornwall and in Brittany the belt of the old Hercynian Mountains of Europe begins. One seems to be the continuation of the other, and such an excellent geologist as Marcel Bertrand maintained that *we have here to deal with the two ends of one very extensive belt of mountains which extended through the North Atlantic Ocean. But we must not forget that the missing link between both ends of these supposed mountain chains is longer than their known extent.* (The italics are mine.)

It seems to me that these and other parts of his lecture throw an interesting light on the theory of the moon's terrestrial origin. In brief, the theory is that when the earth had cooled from its molten condition sufficiently to have a crust of solidified matter something like thirty miles thick over its entire surface, it was revolving so rapidly that gravitational attraction and centrifugal force practically balanced each other. For some reason, perhaps some vast and sudden cataclysm, a large portion of this crust was thrown off the earth, and by tidal action was forced gradually outward in a spiral path. In order to form the moon, a mass of this crust about thirty miles thick and of area nearly equal to the combined areas of the present oceans on the earth must have been thrown off. It is supposed that this immense amount of crust was largely taken from the present basin of the Pacific, and that the remaining parts of the earth's crust, while it still floated on a liquid interior, split along an irregular line into two pieces which floated apart, and the gap between these two parts was later filled

with the waters of the Atlantic. Many reasons are advanced for the probability of this theory—the fact that the two coasts of the Atlantic have the same contour, the identity between the density of the moon and that of the earth-crust, etc. Professor Penck is evidently considering this theory at all in his lecture, and yet it seems that what he, approaching the problem from a geographical standpoint, has to say about it, lends a greater probability to the theory. As he says, the Appalachian region ends at Newfoundland, about the latitude of 50° north, and just opposite, in Great Britain, on the same latitude, the same region seems to continue. If the theory of the terrestrial origin of the moon, outlined above, be accepted, we can explain this phenomenon much more simply than did Bertrand, and need not suppose the range to extend across the bed of the Atlantic at all.

UNIVERSITY OF NORTH CAROLINA

SCIENTIFIC BOOKS

Scientific Ideas of To-day. A popular account of the nature of matter, electricity, light, heat, etc., in non-technical language. By CHARLES R. GIBSON. Pp. 344; illustrated. Philadelphia, J. B. Lippincott Company. 1909.

This book is one which would justify a favorable estimate from almost any other point of view than that which the present reviewer chooses to take. Thus, William E. Rolston gives a favorable estimate of the book in his review of it in *Nature*; indeed many sections of the book are such as to demand a favorable estimate from any point of view. For example, the description in terms of the electron theory of what takes place when glass is rubbed with silk or when zinc is dissolved in a voltaic cell (see pages 73-79) is as clear as any one could wish to have it; and in many cases the "scientific ideas of to-day" which are elaborated in the book are applied at once to the analysis of actual phenomena. But some weeks after looking over the book, I came upon what to me seems to be a very significant paper by Professor William James, "On a

Very Prevalent Abuse of Abstraction,"¹ which happens to express precisely what I wish to say concerning the book and the kind of popular scientific writing which it represents. Professor James says that "to be helped to anticipate consequences is always a gain, and such being the help that abstract concepts give us, it is obvious that their use is fulfilled only when we get back again into concrete particulars by their means." By far the greater portion of the book under review fails to meet this condition of utility, and on the whole the book can not be looked upon as a preliminary step towards a subsequent realization of this idea of utility.

One phase of the author's point of view may be seen in the following quotations: "Water is nothing more or less than a chemical combination of two gases" (page 25); "Chemical affinity is nothing more or less than electrical attraction between different atoms" (page 29); "An electron is nothing more or less than electric charge in motion" (page 51); "An electric current is nothing more or less than an electron current" (page 75); "Light is simply waves in the ether" (page 153); "It must be clearly understood that all atoms of matter are made up of a number of electrons revolving in regular orbits, and that we can not in any way disturb these arrangements" (page 157). As if one could be placed under obligations to clearly understand any physical fact in terms of an extremely vague hypothesis!

Professor James gives the name "vicious abstractionism" to this mode of using concepts. He says:

We can see a concrete situation by singling out some salient or important feature in it, and classifying it under that; then, instead of adding to its previous characters all the positive consequences which the new way of conceiving it may bring, we proceed to use our concept privatively; we reduce the originally rich phenomenon to the naked suggestions of that name abstractly taken, treating it as a case of "nothing but" that concept, and acting as if all the other characters from out of which the concept is abstracted were expunged. Abstraction functioning in this way

becomes a means of arrest far more than a means of advance in thought.

The viciously privative employment of abstract characters seems to be the greatest infirmity of the average mind in scientific work, and books like this of Mr. Gibson's stand for the extension to a wide circle of readers of a hopelessly sterile philosophical by-product of the modern physical sciences.

The authors of such books as "Scientific Ideas of To-day" stand before us, indeed, chiefly in the rôle of teachers; but the teaching of the physical sciences is to a very great extent a matter of exacting constraint, and it can not be accomplished in a manner which is pleasant and popular.

Da wird der Geist Euch wohl dressiert
In spanische Stiefeln eingeschnürt.

The teaching of physical sciences is indeed a compelling insistence upon precise ideas, a forcible "making up" of a student's mind, as it were; for, as Whewell says, nothing is so essential in the acquirement of exact and solid knowledge as the possession of precise ideas, not, indeed, that a perfect precision is necessary as a means of retaining knowledge, but that nothing else so effectually opens the mind for the perception even of the simplest evidences of a subject.

In speaking of the constraint that is involved in genuine science teaching I do not refer to the necessity of overcoming indifference, but to a condition which is real in the face of any amount and any quality of enthusiasm. Every one is of course familiar with the life history of a butterfly, how it lives first as a caterpillar and then undergoes a complete transformation into a winged insect. It is of course evident that the bodily organs of the caterpillar are not at all suited to the needs of a butterfly, the very food (of those species which take food) being entirely different. As a matter of fact, almost every portion of the bodily structure of the butterfly is dissolved into a formless pulp at the beginning of the transformation, and the organization of a flying insect then grows out from a central nucleus very much as a chicken grows in the food-stuff of an egg. So it is in the development of a scientifically trained mind. In early

¹ *Popular Science Monthly*, May, 1909.

childhood, if the individual has been favored by fortune, he exercises and develops more or less extensively the primitive instincts and modes of the race in a free out-door life, and the result is so much mind-stuff to be dissolved and transformed with more or less coercion and under more or less constraint into a mind of the twentieth-century type. The period during which a young man is receiving his scientific and professional training is indeed analogous in many respects to the period of complete reorganization of bodily structure, and in the other we have a reorganization no less complete of mental structure; in the one the reorganization is wholly dependent upon and determined by internal energies, but in the other the reorganization is largely dependent upon and determined by external constraint.

It is a remarkable thing this changing of men into bees and butterflies! and the operation is indeed severe. But perhaps the most remarkable thing about it is that it is elective in particular, but apparently in our day a dire necessity in general, somewhat like the curious transformation of the axolotl, which lives always and reproduces his kind as a tadpole unless a stress of dry weather annihilates his watery world when he lops off his tasseled gills, develops a pair of lungs and embarks on a new mode of life on land.

A severe operation! And usually for the individual a change, like that of the axolotl, from a fluid world to a rigid one! I remember as a boy a sharp contest in my own mind between an extremely vivid sense of things physical and the constraining function of precise ideas. This contest is perennial, but it is not by any means a one-sided contest between mere crudity and refinement, for refinement ignores many things. Indeed precise ideas not only help to form our sense of the world in which we live, but they tend to inhibit sense as well, and a world in which their rule is unchallenged becomes indeed a dry and rigid world.

Every student should realize two things in connection with his science study; the first is that the study of the physical sciences is exacting beyond all compromise, involving as

it does a degree of coercion and constraint which it is beyond the power of any teacher greatly to mitigate; and the second is that the completest science stands abashed before the infinitely complicated and fluid array of phenomena of the material world, except only in the assurance which its method gives. And both of these things are obscured by books like "Scientific Ideas of To-day," books that know nothing of exacting constraint nor ever stand abashed. The attempt to set forth in an easily plausible style the conceptual structure of modern physical science is one of the most troublesome perversions with which one has to deal in the attempt to contribute towards the solution of what is to be perhaps the greatest problem of the twentieth century, namely, the making available to all men of the simpler phases of the logical structure of the sciences in order to give to all men some measure of that clear insight into nature which contributes so greatly to the ordering of one's daily life.

W. S. FRANKLIN

LEHIGH UNIVERSITY

Normentafel zur Entwicklungsgeschichte des Menschen. By FRANZ KEIBEL and CURT ELZE. 4to, 314 pp., 0 pls., and numerous text figs. Jena, Gustav Fischer. 1908.

This eighth volume in Professor Keibel's series of "Normentafeln" is much larger than any of its predecessors, thus reflecting the special interest which mankind takes in human embryology. Like the earlier numbers it consists essentially of a tabular description of embryos, with plates showing their external form, and a classified bibliography. The titles of papers relating to human embryology occupy 150 quarto pages, and yet, of the publications dealing with malformations, only the more comprehensive have been included. The bibliography is so thorough and useful that it renders this "Normentafel" indispensable to every student of vertebrate embryology. The plates are excellent, and show embryos from 1.17 to 24 mm. in length, seen in several positions. The text figures include numerous single sections, and several partial reconstructions of the embryos described. A

complete series of graphic reconstructions would seem to justify the great amount of labor which it requires, and, at the reviewer's suggestion, Mr. R. E. Scammon is preparing such a series for the "Normentafel" of *Squalus acanthias*. In the Harvard Laboratory some progress has been made toward such a series for the pig. This plan has been partly carried out in the "Normentafel" for man, thus adding materially to its value. The text figures accompany the brief descriptions of the various embryos, which precede the tables.

In addition to the descriptions, tables, plates and bibliography, there are three general discussions of great interest. The first (pp. 7-14) is a critical account of the youngest known human embryos. There has been something hardly scientific in the attempt to obtain the "youngest yet known"—in the description of specimens "excessivement jeune," and in monographs on fragments and pathological debris. Keibel's review shows that the two pages written by von Spee, included in Peters's monograph of 143 pages dealing with a single specimen, is at present the most illuminating account of the youngest human embryo. A reconstruction of this specimen, made by Keibel, is described briefly. From the study of Peters's, von Spee's and Keibel's youngest specimens it is inferred that the cavities of the human amnion, yolk-sac and extra-embryonic coelom arise as clefts in solid masses of cells; their development is illustrated in a series of diagrams. An amniotic duct, such as is indicated in Eternod's familiar model, is not found in the younger specimens, and in these there is no neurenteric canal.

The second general chapter (pp. 80-89) includes a comparison of human embryos with those of apes and *Tarsius*. It is found that the youngest stages of man and the apes are very similar, but that they differ materially from *Tarsius* at a corresponding stage. Although the human embryo is very much like that of an orang, "a glance is sufficient to distinguish it from any other well-known form." In this chapter it is stated that the bend in the back of human embryos, such as is seen in the reproductions of the His models

found in most laboratories, is abnormal.

The third section (pp. 152-162) is a comparative embryological study of various structures, based upon the preceding numbers of the "Normentafeln." Thus it is stated that the allantois in man and the apes develops very early, before segments have formed. In *Tarsius* also it arises before there are any segments, but later than in man and the apes. It first appears in pigs of four to five pairs of segments, in rabbits of about eleven pairs and in chicks of more than twenty pairs. Similar comparisons are made for the lungs, pancreas, thyroid gland, etc. A foundation is thus laid for future work in comparative embryology which shall be more accurate and detailed than anything yet realized.

It may be noted that in two human specimens, a fifth pair of pharyngeal pouches was identified, in one case reaching the ectoderm. Fox's recent studies of the pig, cat and rabbit have failed to show a fifth pouch, but Tandler declares that its presence in man is not a morphological speculation—it is an established fact. This question is clearly one which requires further study. In fact the great value of this "Normentafel" is the stimulus and aid which it affords to further research. The need of early human embryos is emphasized. The omission of any account of the muscular and lymphatic systems is conspicuous. But the great progress which has been recently made in human embryology has been compactly recorded. The work is of the utmost practical value, and in a recent discriminating review it has been described as a "masterpiece of scientific effort." It is the only comprehensive account of strictly human embryology which is now available.

FREDERIC T. LEWIS

SPECIAL ARTICLES

NOTICE OF TWO NEW HORIZONS FOR MARINE FOSSILS IN WESTERN PENNSYLVANIA

SINCE the time of the second geological survey of Pennsylvania it has been generally accepted that there are three horizons at which marine fossils may be found in the Conemaugh series of western Pennsylvania. The oldest of these is the Brush Creek limestone, about

100 to 125 feet above the Upper Freeport coal. From 60 to 90 feet above this is the Pine Creek limestone, while the Ames limestone is about 125 feet above the Pine Creek and 300 feet below the Pittsburgh coal. Under various names these limestones have been reported from a large area in western Pennsylvania, northern West Virginia and southeastern Ohio. As these limestones are all very thin and are included in a great mass of shales and sandstones of debatable origin, the discovery of two more layers containing marine fossils is of some interest.

The first of the layers is about 50 feet below the base of the Ames limestone on Brighton Road, just west of Wood's Run, Allegheny, Pa. This stratum was noted by the writer in 1907, but as it was found in only one place, it was thought at the time that it might be a disturbed block of the Ames limestone. It was, however, mentioned in a paper just published in the *Annals of the Carnegie Museum*, Volume V., page 174, and its correct stratigraphic position indicated in the diagram on Plate XII. As exposed at the type-locality on Brighton Road, the fossiliferous layer is about three inches thick and contains numerous crinoid stems, *Producti*, and cup-corals. It is a hard clayey limestone, with most of the lime leached out at the outcrop. It outcrops at a number of places within two miles of this locality, but has not yet been traced to any distance. At some of the other outcrops the layer is thicker, the greatest thickness noted being eighteen inches.

In an article on the Conemaugh formation in southern Ohio just published in the *Ohio Naturalist*, Mr. D. Dale Condit describes a thin marine limestone about half-way between the Ames and the Upper Cambridge limestones. This limestone occupies the same stratigraphic position as the one here described, but as they are separated by a very wide area in which neither has been sought, it is too early to attempt to correlate the two.

The credit for the discovery of the second layer with marine fossils belongs largely to the Rev. P. E. Nordgren, of Duquesne, Pa., who found loose blocks of fossiliferous shale along

the railroad tracks about two miles west of Duquesne. The writer was able to trace these blocks to their source in a layer of green sandy shale at the top of the Birmingham shale. This layer is about 65 feet above the Ames limestone. In the vicinity of Pittsburgh the Birmingham shale is a conspicuous formation in the cliffs which border the rivers. It is from 40 to 50 feet in thickness and the base is about 25 feet above the top of the Ames. At the base of the Birmingham there is always a layer of very thin-bedded black shale, and sometimes a coal which is supposed to represent the Elk Lick. Above this carbonaceous layer are thin-bedded dark shales which contain pinnules and stems of ferns, and numerous *Estherias* and fish-scales. Higher up the shales become lighter colored, often sandy, and are very barren of fossils. The only fossils so far found in these light-colored layers are a few specimens of an *Aviculopecten* like *A. whitei*, a shell which is often found associated with fossil plants. At the top of the Birmingham there is an abrupt change in the color, the upper 8 to 15 feet being a red fissile shale. Just beneath the red shale, or sometimes a few feet above the base of the shale, there is a rather prominent layer of sandy shale which has now been found to contain marine fossils. The fossils are species of *Productus*, *Allorisma* and other pelecypods, and *Tainoceras occidentale*. Fossils have been found in this layer in Riverview Park, Allegheny, below Kenneywood Park near Duquesne, at Glassport, at Wilmerding and at East Pittsburgh. It is most fossiliferous at the locality discovered by Mr. Nordgren below Kenneywood Park, and that should be considered as the type-locality.

In Riverview Park *Aviculopecten* may be found in a layer 25 feet above the layer just described and a further search for fossils may show that the Ames is far from being the last marine deposit in western Pennsylvania.

NEW FACTS ABOUT BACTERIA OF CALIFORNIA SOILS

THE bacteriological study of California soils at this Experiment Station during the past year

marks the beginning of research on the biology of soils of the arid regions. Some of the facts gleaned in these studies present such striking features that it was thought wise to make a brief preliminary report on them in this journal. The facts may be categorically enumerated as follows:

1. Nitrite formation from ammonia compounds formed by the ammonifying bacteria has been found to take place markedly at depths of twelve feet in a soil from Haywards, Cal. Further, in samples gathered under the greatest precautions to avoid contamination, nitrite formation was found to go on actively at a depth of five and one half feet in a soil gathered at Riverside, Cal. Below five and one half feet there was a compact layer of hardpan in which there was little or no bacterial growth and nitrite formation could not, therefore, be expected deeper down in that particular soil. In six other soils collected in different parts of this state nitrite formation was found to depths of six feet or as far down as we had gone for samples.

2. Contrary to expectations *nitrate* formation, unlike nitrite formation, has thus far been noted only down to a depth of two feet. Further experiments, however, will be instituted to ascertain if this holds true for all California soils.

3. A bacteriological examination of a soil from Auburn, kept in a tightly stoppered bottle on the museum shelves for thirty-one years, reveals at least one representative of each of the groups of nitrogen-transforming or nitrogen-assimilating bacteria, except *B. radicicola*. Of these, several species of ammonifiers were found, one species of nitrosomonas (obtained in the motile and also in the zooglæa form) and one species of *Azotobacter*. The latter exhibits marked differences from the other *Azotobacter* species thus far described, both morphologically and physiologically, and it was therefore named *A. hilgardii* in appreciation of the eminent services of Professor E. W. Hilgard to scientific agriculture. Briefly, the organism may be described as a small elliptical cell, which forms no pigment and only a very thin membrane at the

surface of mannite solutions. It is non-motile and has a slight nitrogen-fixing power.

4. The species of nitrosomonas found in the old soil mentioned above was found to have spores. This is particularly interesting, since Winogradsky stated in a report of results of his wonderfully thorough experiments on the nitrifiers, that spores were *never* observed.

No *Nitrobacter* species or nitrate organism has as yet been found in the old soil.

The above facts are probably due chiefly to the great perviousness of the soils of the arid region, owing to the very slow formation of clay substances; whereby moisture, air and roots are enabled to penetrate to depths rarely found in the humid regions.

A SCHEME TO REPRESENT TYPE HEREDITY IN MAN

Efforts to reconcile Mendel's laws with the prevailing views of blended effects in heredity need not be unavailing, if the two may be considered as phases of the same process acting at different times during the life history of an elementary species.¹

Heredity represents all the changes of organic life by three factors:

1. *Determinants*, which are in the germ plasm.

2. *Modifiers*, which are all influences through time and space that act on the germ plasm, and

3. *Laws of change*, which are the rules of conduct by which the determinants and the modifiers interact.

These factors are variable when looked at through all space and during all time, but for any elementary species in a given space and for a limited time they are fixed.

I present herewith a tentative scheme to supplement my theory of heredity.²

D and *R* represent homozygotes of an

¹ Spillman, *Science*, N. S., Vol. XXVII., 1908, pp. 47-57.

² Bean, *Philippine Journal of Science*, 1908.

allelomorphic pair that meet at 1 in sexual union, begin to blend at 2, present the picture of a variable blend at 3, and fuse completely

into a perfect blend at 4. A cross-section of the diagram above line 3 represents the relative number of individuals of the different kinds present at that time. The width of the

diagram also indicates the amount of variation at any time. D = homozygous dominants. R = homozygous recessives. DR = heterozygotes. B^1 = a variable blend ever increasing in number with each successive generation while D , R and DR decrease to disappear entirely at 3. B^2 represents the continuation of the blend without either of the originals of the allelomorphous pair, but with all shades of intervening characters blending in various ways as influenced by ancestry and by environment, until a homozygote is formed at 4.

From 1 to 2 true Mendelism exists, spurious Mendelism is found from 2 to 3, and from 3 to 4 no Mendelism is present but two tendencies prevail, (a) the reversion to type, and (b) the tendency to blend.

The three Mendelian (?) conditions may exist at the same time in a single individual, one character exhibiting true Mendelism, another false and a third no Mendelism, or only one condition may be present at one time.

Davenport and Davenport⁵ have established true Mendelian heredity for eye color in man; Bateson⁶ has designated many conditions in man which indicate spurious Mendelism; and Boas⁷ has suggested the two hereditary tendencies above mentioned, when broad-headed and long-headed, or wide-faced and long-faced individuals are united in marriage.

My records of Negroes, of white students, and of the Filipinos suggest that composite types (elementary species?) of men when crossed with opposite types follow the laws of Mendel for not many generations, then begin to blend, and eventually fulfill the requirements of my scheme delineated above. At present all mixed races are probably in a condition of spurious Mendelism or no Mendelism. Among the Negroes in America the Hottentot is rarely seen, the Kaffir is often encountered, and the Guinea Coast Negro is abundant, but the majority of the Negro population represents a variable blend of different Negro types, and a large number of mixed

bloods. Among 1,000 students at Ann Arbor, I observed a few of each of the types of Europe such as the Iberian, Northern, Alpine, Celt, Littoral and Adriatic, but the majority of the students observed were variable blends, and the pure types were not exactly like the prehistoric types of Europe from which they were probably derived, although similar to them in many ways. During the past year my anthropometric investigations have included the Filipinos of many provinces, but especially the Igorots. Here as elsewhere pure types are rare and blends are plentiful. Three primary types (each represented by 8 or 9 individuals selected from 104 Igorots) are found among the Igorots. None of these are pure, however, but one type resembles the Negrito, another resembles one of the prehistoric types of Europe, while the third is unlike either of the others, but not a blend of the two. The majority of the Igorots represent a variable blend, and they have been so long isolated that a condition of no Mendelism has been reached. There is conclusive evidence of the persistence of type, yet the tendency to blend is emphatic.

PHILIPPINE MEDICAL SCHOOL,
MANILA, P. I.

A NEW EDIBLE SPECIES OF *AMANITA*

DURING the autumn of 1908 I received specimens and sketches of an interesting species of *Amanita* which grows in the mountain forests of California. The specimens were collected and communicated by Mrs. Virginia Garland Ballen, of Brookdale, Santa Cruz County, Cal. The sketches were accompanied by careful notes which Mrs. Ballen had made from her studies and observations. While the plant shows certain points of relationship to *Amanita caesarea*, especially to the robust European form, Mrs. Ballen had recognized that it was different from the American form of *A. caesarea*, which is more slender, and in fact it proves to differ in several ways from that species. The plant is edible and often very large, so that a single one is sufficient for a meal. Pending a fuller illustrated account, a brief description is given here.

Amanita calypetroderma Atkinson and Ballen n. sp. Plants 10-15 cm. high, pileus 10-22 cm. broad, stem 2-4 cm. stout. Pileus maize yellow to chrome yellow; gills white, then pale maize yellow to cream color; annulus and stem pale maize yellow to cream color. Pileus stout, extreme margin striate, the central and larger portion covered with the closely adherent white calyptra of the volva; in age of the larger plants this calyptra sometimes cracking into areas. Gills adnexed. Spores oval to elliptical, $8-12 \times 7-8 \mu$. Annulus very thin, membranaceous, superior, evanescent. Stem hollow with loose cottony threads. Volva white, thick, circumscissile, in dehiscence, the upper portion remaining as a thick skin over the central portion of the pileus; limb very prominent, forming a broad cup- or saucer-shaped structure from which the stem of old plants often separates readily.

GEO. F. ATKINSON

THE AMERICAN ASSOCIATION OF MUSEUMS

THE fourth annual meeting of the American Association of Museums was held in Philadelphia, May 11-13, President W. J. Holland, director of the Carnegie Museum in Pittsburgh, presiding. The following papers were read:

"Cooperation in Scientific and Educational Work between Museums," by President William J. Holland.

"Cooperation among College Museums," by Dr. Daniel S. Martin.

"Cooperation between Museums in Expert Work," by Dr. Edwin A. Barber. (Read by title only.)

"The New Staten Island Museum and its Work," by Mr. Charles Louis Pollard.

"The Insect Pests of Museums," by Mr. C. T. Brues. (Read by title only.)

"Invertebrate Models and Exhibition Groups," by Mr. Roy W. Miner. (Illustrated.)

"The Children's Museum, its Methods of Work and its Results," by Miss Anna Billings Gallup. (Illustrated.)

"The Use of Unkerhelmer's Solution for Preservation of Natural Foliage," by Mr. Adolphe B. Covert. (Illustrated.)

"The Darwin Exhibit at the American Museum of Natural History," by Mr. Roy W. Miner. (Read by title only.)

"The British Guiana Expedition of Indiana University and the Carnegie Museum," by Dr. C. H. Eigenmann. (Illustrated.)

"A New Museum Case," by Dr. Hermon C. Bumpus.

"The Educational Work of the Buffalo Society of Natural Sciences," by Mr. Henry R. Howland.

"Suggestions for an Educational Exhibit of the Mollusca," by Mr. Frank C. Baker.

"Present Educational Work of the Philadelphia Museums," by Mr. Chas. R. Toothaker.

"What shall we do with our Skeletons and our Fossils?" by Mr. Henry L. Ward. (Read by title only.)

"The History of Commerce in Museums," by Mr. W. H. Schoff.

"Photographic Enlarging Methods," by Mr. Fred. D. Maisch.

"The Adaptation of a Library to a Commercial and Economic Museum," by Mr. John J. Macfarlane.

"Some of the Most Recent Museum Instruments and Appliances," by Dr. M. J. Greenman.

"The Planning and Fitting of Exhibition Rooms, Especially Picture Galleries," by Mr. Wm. M. R. French.

"Art Museums and the Conservation of Monuments," by Mr. Benjamin Ives Gilman.

"The Desirable Projection of Art Museums as suggested by the Desirable Classification of Art Libraries," by Mr. William H. Goodyear.

"The Training of Curators," by Mrs. Cornelius Stevenson.

"Problems of Modernizing an Old Museum," by Mr. Witmer Stone.

"Exhibition Cases without Shelves," by Mr. Frank C. Baker.

"A Device for exhibiting Fodible Minerals," by Dr. Oliver C. Farrington.

"The Uses of a Collection of Historical Coins," by Dr. T. L. Compagette.

"Popular *versus* Scientific Arrangement of Museum Exhibits," by Dr. James E. Talmage.

"Special Work of a State Museum," by Dr. A. R. Crook.

"Progress of the Ohio Archeological Atlas," by Professor William C. Mills.

These papers will appear in full in the annual volume of proceedings, to be published by the secretary during the summer.

The following officers were elected by the association:

President—Frederic A. Lucas, curator-in-chief

of the Museums of the Brooklyn Institute of Arts and Sciences.

First Vice-president—Frederick J. V. Skiff, director of the Field Museum of Natural History, Chicago.

Second Vice-president—Edward S. Morse, director of the Peabody Museum, Salem, Mass.

Secretary—Paul M. Rea, director of the Charleston Museum, Charleston, S. C.

Treasurer—William P. Wilson, director of the Philadelphia Museums, Philadelphia.

Councillors (to serve for three years)—James E. Talmage, director of the Deseret Museum, Salt Lake City, Utah; William J. Holland, director of the Carnegie Museum, Pittsburgh.

The fifth annual meeting will be held in Buffalo in 1910.

The association is preparing "A Directory of Museums of Art, History and Science in North and South America," and all museums which have not received circulars requesting information for incorporation in this work are urged to communicate at once with the secretary.

PAUL M. REA,
Secretary

THE CHARLESTON MUSEUM,
CHARLESTON, S. C.

SOCIETIES AND ACADEMIES

THE GEOLOGICAL SOCIETY OF WASHINGTON

At the 215th meeting of the society, held at the Cosmos Club, on Wednesday evening, February 24, 1909, Mr. David White presented an informal communication on the "Occurrence of Resin in Paleozoic Coals," and exhibited specimens of such fossil resins from the Coal Measures of Iowa, Illinois and Indiana. Amber and other fossil resins occur mostly in Mesozoic and Tertiary coals that have not been much altered, but in coals that have suffered regional metamorphism they are as a rule absent. Where devolatilization has advanced so far that the percentage of fixed carbon is 85 or more they are seldom found.

Regular Program

Correlation of the Rocks of the Boston Region:
LAURENCE LAFORGE.

After a brief résumé of the development of the current ideas on the subject, the following outline grouping of the various rocks was described.

There are two series of sediments, Cambrian and Carboniferous. For the fossiliferous beds of lower Cambrian age the name Weymouth formation has been proposed, while the Braintree slate contains a

middle Cambrian fauna, and there is a non-fossiliferous group of quartzites, schists and hornfels, which may be of any age from lower Cambrian to Ordovician. The Carboniferous sediments comprise the so-called Roxbury conglomerate and Cambridge slate.

About forty varieties of igneous rocks are separated into the following groups on the basis of consanguinity, association and structural relations: (1) a "gabbroic" group, including gabbro, basalt, diorite, amphibolite, etc., of presumably Ordovician age, and represented in the diorite complex of Swampscott, etc.; (2) a "tonalitic" group, comprising granite, tonalite and diorite, probably post-Ordovician and pre-Carboniferous, and represented by the granites of Saugus and Dedham, etc.; (3) a "felsitic" group, a complex of felsites, granophyres, tuffs and breccias, of early Carboniferous age, and covering several large areas; (4) a "granitic" group, including granite, quartz porphyry, nordmarkite, etc., represented by the granites of Quincy and Peabody, etc., of Carboniferous age and possibly contemporaneous with the "felsitic" group; (5) a "basaltic" group, represented by the "Brighton amygdaloid," of Carboniferous age, and (6) a "diabasic" group, comprising hundreds of dikes of Triassic age. There are also some pre-Triassic diabbases, of as yet uncertain age.

Fluidal Gneiss and Contemporary Pegmatites:
WHITMAN CROSS.

In the Needles Mountain pre-Cambrian area in southwestern Colorado there are several granitic batholiths. One of these, called the Twilight granite mass, is intruded in most intricate fashion in steeply upturned Archean amphibole schists.

Both gneissic and schistose textures are exhibited in the intrusive granite. The former is a fluidal texture originating during the consolidation of the granite. Such textures curve in and out among amphibole schist fragments, the sharp angles of which are notable. Where a secondary schistose texture occurs the amphibole schist and granite are both crushed and sheared and it is difficult to determine in certain localities which is the intrusive rock.

Pegmatite occurs as a phase of the granite in arms penetrating amphibole schist or in relatively small dikes connecting larger gneissoid bodies. The transition of the pegmatite into gneissoid granite or granular rock and the absence of pegmatitic dikes cutting the latter show that the pegmatite is practically contemporaneous with the granite. None of these pegmatite masses is more

than a few inches wide and the minerals are those of the biotite granite.

Pleistocene Geology of the Leadville Quadrangle, Colorado: S. R. CAPPS.

The work was commenced in 1903 with E. K. Leffingwell, and completed the following summer with the assistance of J. M. Hill and C. A. Kirtley. Of the 950 square miles of the quadrangle, more than 350 square miles have been glaciated. In this area 36 ancient valley glaciers were studied and mapped. Moraines of two distinct epochs of glaciation, one much older than the other, were found. The ice of the earlier epoch covered approximately the same areas as that of the later one.

The great terraces near Leadville, which have hitherto been referred to as lake beds, are probably remnants of compound alluvial fans, deposited as outwash from the older glaciers. This conclusion is based upon the imperfect stratification of the materials, their lack of lake bed structures, the absence of shore lines, and upon the similarity in structure to present alluvial fans. The terraces also show the same amount of weathering as the older moraines, and the topographic relation between the terraces and these moraines is significant. Lower terraces were found which bear similar relations to the moraines left by the last glaciers. The courses of the Eagle River above Redcliff, and of the Arkansas River, near Granite, have been altered as the result of obstruction by the glaciers.

FRANCOIS E. MATTHES,
Secretary

At the 216th meeting of the society, held at the Cosmos Club on Wednesday evening, March 10, 1909, Mr. Wirt Tassin presented an informal communication on "A Method of Illumination for the Study of Opaque Substances under the Microscope," and showed the apparatus for same in operation.

Mr. F. E. Matthes, on behalf of Mr. R. H. Chapman, gave a brief communication on the Cullinan diamond, and showed glass models of the stone in the rough and of some of the larger gems cut from it.

Regular Program

Primary Soapstone in Igneous Rocks: F. C. CALKINS.

In the Philipsburg quadrangle, in western Montana, a thick series of sediments, largely calcareous, is invaded by batholiths of rocks allied

to quartz monzonite. Associated with some of these batholiths as marginal facies, as small stock-like masses, and as dikes cutting both igneous and sedimentary rocks, are rocks of aplitic habit characterized by the presence of lime-soda feldspar usually in excess of alkali feldspar, a diopsidic pyroxene, and abundant titanite. Some contain scapolite; in one instance this mineral formed about 20 per cent. of the rock. In this rock the scapolite encloses all the other minerals and interpenetrates with all but quartz and the minor accessories, so that there is no doubt of its primary character. Chemical analyses of two of the scapolite-bearing rocks show the remarkable combination of rather high SiO_2 , low MgO and iron oxides, with high CaO and Na_2O ; chlorine is more abundant than in most rocks. It is surmised that these unusual rocks have been formed by the solution of limestone in magmas of aplitic composition containing abundant chlorine. No partial stages of the assimilation have been observed, and it probably took place at great depths.

On the Origin of Peat: CHARLES A. DAVIS.

Peat deposits are formed: (1) in depressions below the ground water level, (2) on poorly drained land areas where the ground water level is near but usually below the surface. Deposits on slopes in regions of high atmospheric humidity and on subsiding coasts are included in (2).

In (1) the peat is formed mainly from aquatic plants, including microscopic algae, the true aquatic higher plants, and a little drift material from the shores. As the peat approaches the water surface, amphibious plants, particularly sedges, other herbs and shrubs, grow out over it from the shore, and form a partly or wholly floating mat, which, later, is invaded by terrestrial plants, including sedges, grasses, ferns, shrubs, sphagnum moss and trees, in the order given. The time when each type appears depends on the height of the surface of the mat above the average water level. Peat formation may go on until the basin is filled, or its surface covered.

In (2) the plants forming the peat are mainly terrestrial, but the types chiefly contributing are controlled by the average height of the ground water level, and climatic conditions. If the ground water level rises with the peat, the entire deposit may be homogeneous, and formed by the same kind of plants; if it remains fixed, the bed is generally thin and varies from bottom to top; if the water rises periodically, the deposit is heterogeneous, with beds of the same structure repeated at intervals.

Decomposition of vegetable matter into peat is principally due to the activities of organisms, the most important being aerobic, hence the top strata of wet peat beds are usually most thoroughly decomposed.

The Landslide at Frank, Alberta: L. D. BURLING.

At 4:10 A.M., April 29, 1903, an amount of rock variously estimated at from 60,000,000 to 100,000,000 tons dropped away from the northeast face of Turtle Mountain, fell through a maximum vertical distance of 3,500 feet, and covered over a square mile of the valley bottom to an average depth of thirty to fifty feet. The slide wiped out the tippie work and buildings of a coal mine at the foot of the mountain, demolished eight houses and a number of smaller shacks and tents, destroyed about two miles of railroad track and killed about seventy people.

Turtle Mountain is an isolated mass situated just south of the Canadian Pacific Railway east of the Continental Divide between British Columbia and Alberta, and towers 3,000 feet above the town of Frank, which lies at its base. The upper part of the mountain is composed of massive upper Paleozoic limestones which dip westward at angles of 20 to 30 degrees. These limestones are thrust over nearly vertical shales and sandstones of Cretaceous age containing a workable coal seam twelve to sixteen feet thick. The strikes of the massive limestones, the thrust plane and the coal beds are very nearly parallel, and for a distance of three quarters of a mile (entirely across the face of the mountain) and for a vertical height of 300 to 400 feet, the entire coal bed had been either loosened or completely withdrawn.

The slide affected only the limestones above the thrust plane. The horizontal distance between the present crest of the mountain and the toe of the slide is nearly two miles, the maximum vertical difference 3,000 feet and the vertical distance between the crest and the toe 2,525 feet. The slope from the crest of the mountain to the lake at its foot is 32 degrees, the first thousand feet having a slope of about 65 degrees. From a width of 2,000 feet at the crest the talus has a width of nearly a mile at the lake, and with minor variations this width is continued to the hills opposite, a mile away.

Whatever may have been the immediate cause of the disaster—the period was one of frequent and marked alternate freeze and thaw, and seventeen men were at work in the coal mine at the time—cracks had been noticed on the back slope

of the former precipitous peak and the slide may have been brought about by some, if not most, of the following contributory causes: (1) the massive limestones forming the upper two thirds of the mountain had been thrust out over the underlying softer shales and sandstones, and therefore may have been in a state of more or less unstable equilibrium; (2) a considerable layer at the base of the massive limestones had been brecciated by the thrust faulting and had thus lost its homogeneity and competency; (3) the limestones forming the upper part of the mountain were very massive and thus more liable to accumulate strain and to give way in a body than would have been the case with weaker rocks; and (4) the opening up of so thick a coal seam, to such a height and for so long a distance in a direction perpendicular to the dip of the massive overlying beds, in rocks incompetent to withstand the pressure thus induced, created strains in the massive rocks from which the support had been removed.

PHILIP S. SMITH,
Secretary

At the 217th meeting of the society, held at the Cosmos Club on Wednesday evening, March 24, 1909, under informal communications, Dr. J. W. Spencer presented briefly some notes on the "Recent Draining of Niagara Falls."

Regular Program

The Composition of Stony Meteorites: GEO. P. MEERILL.

The average of a large number of analyses of stony meteorites shows close agreement, after the elimination of the metallic iron, with terrestrial peridotites. From a magma of this kind no amount of magmatic differentiation could produce a series of rocks as rich in silica, alumina, lime and alkalis as those shown by the averages calculated by Clarke and Washington to be characteristic of the earth's crust. World origin through the segregation of materials of this nature is therefore impossible. At the same time it may be conceived that the relative proportion of the elements which make up the mineral matter in the various bodies wandering in remote space, varies widely. If this is so, the earth to-day, in its course, may be passing through and receiving from space deposits of material representing one and the same original body, but not necessarily resembling, in percentage composition, the materials which reached it during past and earlier

stages of the earth's history. In brief, the stony meteorites may be regarded as products of an extremely basic phase of magmatic differentiation from a previously more acid magma.

Chemical Composition as a Criterion in Identifying Metamorphosed Sediments: E. S. BASTIN.

Chemical criteria need seldom be resorted to for the identification of metamorphosed sediments of a highly siliceous or a highly calcareous nature. They are inapplicable for the identification of many of the metamorphic equivalents of the arkoses, greywackes and similar rocks, since these may be almost identical in composition with the igneous rocks from which they have been derived. Chemical criteria are also inapplicable in the recognition of flow gneisses and of injection gneisses. Such criteria are therefore restricted in their usefulness for the most part to the differentiation of metamorphosed equivalents of the argillaceous sediments from metamorphosed plutonic and volcanic rocks.

The available analyses of metamorphosed igneous rocks show that well-developed foliated structures may in many cases be developed without important chemical changes, and it seems probable that in a very large number, if not in most, of the metamorphosed igneous rocks with which the geologist has to deal the chemical changes during metamorphism have not been severe enough to obscure their igneous characters. They are in many instances still igneous rocks in composition, and the chemical criteria for distinguishing them from metamorphosed sediments may be brought out by a comparison of the latter with normal igneous rocks as tabulated in Washington's tables of analyses.

The chemical characteristics of the argillaceous sediments and the changes they undergo during metamorphism may be determined by a comparison of the averages of a large number of analyses of clays, shales, slates and schists. By comparing these sedimentary averages with the igneous rocks as tabulated in Washington's tables of rock analyses, the following chemical characteristics are shown to be suggestive of sedimentary origin.

1. Excess of alumina (Al_2O_3) above the amount necessary to satisfy the ratio of 1 to 1 with which it is normally combined with lime and alkalis in igneous rocks.
2. Excess of magnesia over lime ($MgO > CaO$).
3. Excess of potash over soda ($K_2O > Na_2O$).
4. In some instances, excess of silica (SiO_2) has confirmatory critical value.

The evidence of sedimentary origin is greatly

strengthened when two or more of the relationships outlined above exist.

The general conclusion reached may be stated as follows: Both igneous and sedimentary rocks undergo chemical changes during dynamic metamorphism. Such changes in the sedimentary rocks are of considerable magnitude and their character is fairly well known. In the igneous rocks changes during dynamic metamorphism appear to be of much lesser magnitude and their character is not so well understood. The lesser degree of chemical alteration that they undergo as compared with the sediments makes it possible to distinguish between the two in many instances on chemical grounds.

Copper-bearing Amygdaloids of the White River Region, Alaska: ADOLPH KNOPF.

The copper-bearing rocks of the White River region, Alaska, comprise a stratiform succession of basaltic amygdaloids, porphyritic sheets, tuffs and breccias, several thousand feet thick, and constitute the dominant portion of a formation of Carboniferous age. In places the amygdaloids are highly zeolitic, and the zeolites form from 25 to 50 per cent. of the bulk of the rock. Native copper has been found intergrown with prehnite, calcite and zeolites filling the vacuoles in the ancient lavas. At some localities veinlets of chalcocite and laumontite cut the volcanics; at others there occur drusy veinlets consisting of quartz, chalcocite and a black combustible mineral, which when ignited burns with a smoky yellow flame. Veinlets of spherulitic prehnite intergrown with calcite and flecked with native copper and chalcocite, also traverse the amygdaloids. The association of a carbon mineral with cupriferous zeolitic amygdaloids appears to be a novel feature, and it is believed to afford a satisfactory explanation for the precipitation of the metallic copper from the mineral-bearing solutions.

FRANCOIS E. MATHES,
Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 665th meeting was held in the afternoon of April 26, Vice-president Day in the chair.

At this meeting, which was complimentary to the American Physical Society, Professor Dr. Max Planck, of Berlin, addressed the society, by invitation, his subject being "Die Mechanik als Grundlage der Physik."

THE 666th meeting was held on May 8, 1900, Past-president Marvin in the chair. Two papers were read.

The Star List of the American Ephemeris: MILTON UPDEGRAFF, U. S. Naval Observatory.

Professor Updegraff gave an account of the star list of the "American Ephemeris" as contained in the first volume of that publication, which is for the year 1855, and also of the star lists contained in the five other national ephemerides of that date. He gave in detail the features of the star list of the "American Ephemeris" and "Nautical Almanac" as it will appear in the volume for the year 1912. The number of stars is to be 825: 800 ten-day stars, 15 northern circumpolar stars and 10 southern circumpolar stars; all circumpolars having their apparent places given for every day in the year. Provision will be made for convenient computation of the effect of the short terms of the nutation for each of the ephemerides of the ten-day stars. These short terms at their maxima and minima have an effect in declination of about a tenth of a second of arc, and in right ascension of nearly a hundredth of a second of time multiplied by the tangent of the declination, and are sufficiently large to make it necessary to take them into account in the more accurate kinds of astronomical work.

Attention was called to the fact that in the "American Ephemeris" the short terms have been included in the Besselian and independent star numbers since the volume for the year 1882, and this fact makes it desirable that the effect of these terms should also be allowed for in the ten-day ephemerides of the stars, although they can not be included directly, as the variation is so rapid as to render interpolation impossible.

A brief account was also given of the star lists contained in the issues for 1910 of the four other national ephemerides. Attention was called to the fact that in the new star list of the "American Ephemeris" the constants adopted by the Paris Conference of the directors of national ephemerides, held in 1896, have been used instead of the Struve-Peters constants which have hitherto been used in the "American Ephemeris," excepting the volume for the year 1900, in which the conference constants were used.

An account was also given of Professor Newcomb's suggested list of fundamental stars, which is now used as the basis of the star lists of all the national ephemerides excepting the *Berliner Jahrbuch*.

The Solar Parallax from Observations on the Planet Eros: C. W. FREDERICK, U. S. Naval Observatory.

The discovery of the planet Eros in 1898 gave astronomers an opportunity to make a more accurate determination of the solar parallax, as the new asteroid approached nearer the earth than any other heavenly body except the moon. Accordingly a campaign was planned for the winter of 1900-1, nearly fifty observatories taking part in the work of observing the planet. The reduction of the observations made at Washington has recently been completed, and the resulting value of the solar parallax is $\pi = 8''.808$ with a probable error of $\pm 0''.012$. This indicates a value greater than $8''.800$, which is contrary to the expectation of astronomers.

R. L. FARIS,
Secretary

* THE AMERICAN CHEMICAL SOCIETY
NEW YORK SECTION

THE last regular meeting of the session of 1908-9 was held on May 14.

The following papers were read:

"The Synthesis of 1, 3, 7, 9 Naphthotetrazines," by A. H. Kroppf.

"Peptic Digestion in Aqueous Solutions of Pure Acid Salts," by R. A. Gortner and A. H. Kroppf.

"The Change in Refractive Index with Temperature," by K. Geo. Falk.

"Investigations on the Relative Value of Several Nitrogenous Materials as a Source of Nitrogen to Crops," E. B. Voorhees and J. G. Lipman.

"The Solubility of Salts in Concentrated Acids," by A. E. Hill and J. P. Simmons.

"Congo Blue—Is it a Free Base or a Salt? Congo White—an Aniline Salt of Congo Blue," by I. W. Fay.

"Soluble and Fusible Resinous Condensation Products of Formaldehyde and Phenol," by L. H. Baekeland.

The Rules for the award of the Nichols medal adopted by the New York Section, June 10, 1904, were amended to read as follows:

Rules for the Award of the Nichols Medal
(adopted by the New York Section, June 10, 1904; amended, May 14, 1909).

1. A Nichols medal or medals shall be awarded annually for the best paper presented to the New York Section during the previous season, provided the paper is of sufficient merit. The award may be made to any one, whether a member of the society or not, if the paper is eligible under the following conditions:

(a) The paper must embody the results of original research in chemistry, which results shall not

have been made public before their presentation to the New York Section.

(b) The paper must be presented at a stated meeting of the New York Section between the first day of October and the fifteenth day of June.

(c) The paper must be presented in its completed form, unless otherwise specially authorized by the executive committee.

(d) Within thirty days after being read before the New York Section, the completed manuscript shall be transmitted to the editor of that one of the society's journals for which the paper seems most appropriate.

2. The jury to determine the best paper among those eligible for the award under the above conditions, shall consist of the editors of the society's publications together with such of the associate editors as they may invite to act with them. The editor of the *Journal of the American Chemical Society* shall be the chairman of this jury. Should the jury thus authorized decline to serve, the executive committee of the New York Section shall designate another jury. The jury shall report their decision to the executive committee of the New York Section, who shall have power to decide whether the paper selected is worthy of the award.

3. The secretary of the New York Section shall send to the editor of the *Journal of the American Chemical Society*, as chairman of the above jury, on or before July 1 of every year, a list of the papers which are eligible under the above conditions, with the request that said jury report to the executive committee of the New York Section by the fifteenth of September next following.

4. In case the paper selected for the award is the work of more than one author, the executive committee may present a medal to every author, the names of all the authors being engraved on each medal.

5. The medal or medals shall be presented at the regular October meeting of the section, or as soon thereafter as may be possible.

6. The executive committee shall have power to decide any question not specifically covered by these rules.

7. Any motion to change or amend these rules must be submitted to the section in writing at least one month before being put to a vote, and notice of the proposed change must be made public at the same time and in the same manner as announcement of the meeting at which the motion is to be put.

C. M. JORDAN,
Secretary

THE PHYSICS TEACHER'S PROBLEM¹

THAT physical science is constantly rendering most magnificent service to human life was never more dramatically demonstrated than on the occasion of the recent wreck of the steamship *Republic*. That a ship, disabled and hidden in a dense fog, was yet able to summon to its aid another ship a hundred miles away by an inaudible, invisible, yet infallible means of communication, thereby saving many hundred lives, is a feat that would have been pronounced impossible by our grandfathers if not by ourselves but a few years ago. Had Mr. Binns, the operator of the wireless telegraph on the *Republic*, lived near Boston about two hundred and twenty years ago, he would surely have been burned for witchcraft.

So thick and fast have come such contributions of science to our commercial and economic life, that most people now take them as a matter of course. A telephone is at present almost as much of a household necessity as a kitchen stove. The steam engine and the electric motor, since by their aid ten men can do the work of one hundred, are increasing our potential manufacturing population at a rate that must satisfy even President Roosevelt that we are in no immediate danger of dying out as a nation. Musicians are being replaced by arc lights, or by pianolas; and even teachers are being compelled to yield their divine calling to graphophones in the "teaching" of foreign languages. Are we then surprised that this is called a scientific age? Do we wonder that scientists are

¹ Address delivered at the Fourth Annual Conference of the Schools of Vermont with the University of Vermont, March 12, 1909.

deeply fascinated by their work, or that the public stand in awe of it?

Yet in the midst of all this, our glory, we must not fail to pause now and then to recall that story of that greatest of astronomers, Laplace. When he had reduced the cosmos to a set of differential equations, by which he claimed that he could foretell the configuration of the universe at any time if he had given the configuration at some other time, he presented his work to Napoleon. After listening to an exposition by Laplace of the meaning of the work, Napoleon remarked: "But I see no place for God in your system." To which Laplace replied: "Sire, I have no need of such an hypothesis."

Suppose some modern Napoleon should, after examining the present formulations of scientific creed, remark: "But I see no place for human souls in this system"; what could science answer? Much it has surely done for the human body; what has it done—what is it doing for the human soul?

A careful investigation of this question seems to show that the distinctive services of science to the human soul may be resumed in two statements, namely: (1) In developing science through the study of nature, the human mind has been trained in clear thinking—it has learned how to solve problems in such a way as to gain for itself the keen vision of a prophet. (2) The clear-sighted experimental study and the partial solution of the problems of nature have continually stored the mind with images which are definite because drawn from concrete experience, and which may thus serve as the basis for clearer abstract thought.

The first of these statements will probably be accepted at once. We all recognize that the power to foresee what will happen under given conditions is one of the chief benefits derived from scientific thinking;

and, therefore, we find no difficulty in appreciating the value of a training in this method of thought. The second statement may not be accepted so readily. Yet it must be clear that such basal concepts as angle, area, number and triangle were derived from experience with and the solving of the problems of nature. The idea means more than this, however. The concrete pictures furnished by the solution of scientific problems are essential to clear thinking in other fields than those of science. It has often been said that if no regularity or order were manifested in nature, no thinking at all would be possible. The clear picture of a sequence and order in nature, yet independent of man's will, is of inestimable moral value. So many of us think that we may steal or lie and yet somehow evade the results. Natural science gives a very definite picture of the impossibility of this. The concrete picture of the sun-centered planetary system has been indispensable in the development of the idea of a God-centered religion. Was not Drummond's book called "Natural Law in the Spiritual World"? Are not most of the similes and metaphors of literature to-day drawn from the clear images furnished by science?

If the two statements just given set forth the two great contributions of science to the civilized mind of to-day, we are justified in setting them up as expressing the purposes to be attained in the individual by science teaching in the schools. We may thus define the purposes of science teaching to be the following: (1) To train the individual into habits of solving problems scientifically, thereby fostering the prophetic spirit in him. (2) To store his mind with clear pictures of organization, which pictures may be used as the basis of abstract thought.

Having adopted these two purposes as the ideal toward which we are to strive in

our teaching of science, we must ask: What criteria have we for testing the results of the work? How are we able to tell whether we are approaching the attainment of these purposes with our teaching? There are two questions which we may put to ourselves if we wish to test our success in attaining these purposes—one for each purpose. First we must ask: Did the problem arise within and out of the student's own experience so that he has a genuine interest in its solution? Is it in some way vitally connected with his life, so that he has an inner motive for its solution? Unless this condition is met, unless the student has real interest in the work put before him, he will get no real training and discipline from it.

The importance of this point has been made very clear by Professor John Dewey in his paper on "Interest as Related to Will"—a paper which has been justly called a supreme court decision on this matter. Professor Dewey says (page 32):

Just because interest is an outreaching thing, a thing of growth and expansion in the realization of impulse, there can be no conflict between its genuine utilization and the securing of that power and efficiency which mark the trained mind—which constitute real "discipline." Because interests are something that have to be *worked out* in life and not merely indulged in themselves, there is plenty of room for difficulties and obstacles which have to be overcome, and whose overcoming forms "will" and develops the flexible and firm fiber of character. To *realize* an interest means to *do* something, and in the doing resistance is met and must be faced. Only difficulties are now intrinsic; they are significant; their meaning is appreciated because they are felt in their relation to the impulse or habit to whose outworking they are relevant. Moreover, for this reason there is motive to gird up one's self to meet and persistently to deal with the difficulties, instead of getting discouraged at once, or half-consciously resorting to some method of evasion, or having to resort to extraneous motives of hope and fear—motives which, because external, do not train "will," but only lead to dependence upon others.

What a different picture this gives from that drawn by those who think interest means amusement; and who, therefore, drive their students by means of motives of hope or fear through unrelated quantitative experiments with the idea that they are giving them discipline!

The second question that we should ask in test of our work is: Are the concepts with which the student is working clear to him? Is the final picture clear, so that clear thinking on his part has been possible? This question needs no further explanation.

Each teacher must answer the first of these questions for himself; no outside person can possibly answer it for him, nor can it be settled by either examination or inspection from the outside. Speaking for myself, then, I may say that for more than three quarters of every class I have, I must answer it in the negative. The majority of each class is attending and pretending to work because of some secondary motive—a college requirement, a desire for credits with a minimum amount of work, a wish to fill an hour in the program, or something of the sort. Comparatively few are there because of an inner interest that impels to good work; and many who might become interested are repelled by the fact that the course is cut and dried, the experiments set up so as to give the student a minimum of obstacles to overcome and a minimum of thinking to do. The testimony of a large number of my colleagues has led me to the belief that this condition is very general—that there are few, if any, teachers whose class as a whole is working spontaneously from genuine interest as defined above. The added testimony of a large number of high-school principals and college deans, who assist the students in the selection of their courses, has made me believe that a large majority of the students shun science courses whenever possible; not because they

are "hard," but because they offer them no chance of expressing their own inner self in new materials—of molding their environment to their scientific imaginations.

The second of these questions above—that concerning the clearness of the concepts—may be answered, at least superficially, by examinations and inspection; and the answer is an unequivocal "no." I am sure that every teacher of physics will agree with me when I say that an examination paper on which there is no utterly foolish statement is a great rarity. The questions asked in class show the same lack of clearness, as has been very forcibly shown by Mr. H. L. Terry in the *Educational Review*, January, 1909. Has any one found a means of making the students discriminate clearly between force, work and power, for example? Here are some examples of what is meant, taken from some recent prize examination papers submitted in competition for a scholarship at the University of Chicago. The competitors were the best students in neighboring high schools. "According to Archimedes' principle, the buoyant force of the water is equal to the volume of the water displaced." "Work is the amount of force that is spent on a certain object, neglectful of time." "Efficiency of a machine is the amount of power received divided by the amount of force exerted upon it." "By Archimedes' principle a body displaces its own weight in water." "The wave-length of red light is longer because in the aurora red light stands out more than does green light."

The fact that from 60 to 70 per cent. of the candidates in physics fail to pass the written examination of the college entrance board each year is eloquent testimony to the same effect.

As the result of a long and careful study of this subject, I can not myself avoid the conclusion that the teaching of physics is

not having even a fair degree of success in attaining the purposes stated above. Any one who accepts these purposes as his ideal, must, I believe, concur in this opinion. That others may have other ideals and purposes in teaching physics, has been abundantly shown by the work of the physics commission. In Circular III. we find that 130 teachers suggested 28 different purposes of teaching physics; some suggesting more than one, but not more than 30 agreeing on any one. Thus some few avow that passing examinations is their purpose: others make "mental discipline" the fundamental aim—meaning thereby the teaching of students to do what they do not want to do because they will have to do so the rest of their lives: thus only may physics become a preparation for grim life. Still others may have the end of teaching the laws and principles of physics; by which is meant bringing the student to the point where he is able to recite and write the statements of these laws, even though he may not be able to show that he possesses clear concepts of the physical quantities related by the laws, or of the relations they describe. Thus he who has other purposes in teaching science may justly believe that physics teaching is satisfactory; but he who accepts as his highest ideal the purposes stated above, must acknowledge that the greater part of physics teaching at the present time fails, to a greater or less extent, to attain those purposes. The teaching of physics is not on that account useless altogether: it is only that it might be a real creative power in education instead of a mere adjunct.

The physics teacher's problem is now before you. It may be stated thus: How shall courses and instruction be modified so as to make the work more nearly approach to the teaching purposes? We teachers

² *School Science and Mathematics*, November, 1906.

shall, of course, have to solve this problem by experiment. We have got to learn first of all to apply the methods of our subject to our teaching problem; we must each and all of us preserve a frankly open-minded and questioning attitude toward our work, and be ever ready to experiment and to make changes in our methods when we find them faulty. We must not cease asking ourselves test questions like those given above, and should regard the students as our real materials for investigation.

But the problem before us, as thus far stated, is too general and vague. We must be more specific, and show just where improvement is most needed. Before making the problem more specific, I want to point out that there are two serious obstacles that confront every teacher who wishes to undertake experimental scientific work along this line. One of these obstacles is an administrative one, due to the school system in general; this obstacle is controlled by forces outside the teacher. The other is a psychological obstacle, due to the past habits of the teacher himself; and to the failure on the part of teachers generally to have definite notions of the meanings of words like interest, discipline, qualitative, quantitative, mathematical, abstract, physics, law, principle and so on.

Time forbids that we discuss these obstacles in detail. Yet they must be removed before the physics teachers will be free to attack their real problem effectively. I will merely state specifically what they are and what is being done to remove them. The first obstacle consists in the systems of regulations that exist for the purpose of securing uniformity of work, whether for college entrance or otherwise. They are not aimed at securing uniformity of good teaching—if they were, there would be no complaint. They attempt to secure uniformity of subject matter. To any one who

studies the system from the point of view of educational value to the individual student, it can not fail to appear injurious and subversive of the ends it tries to reach, namely, vital study. It makes but little difference whether such systems are maintained by examination, or by accrediting, or by state law. The injury comes from the fact that the subject matter of the course of study is specified in minute detail by some authority outside the school and hence unfamiliar with local conditions, particularly the motives and interests of the particular students concerned. The outside authority may be either a board of regents, a committee of some association or a group of colleges, without in any way lessening the evil effect of seriously hampering the teacher in the use of his own initiative and in his attempts to meet local and individual needs. A certain degree of uniformity is certainly desirable; but a bare outline of the larger phases of the subject suffices for this, and avoids the very grave injury that is sure to result to the students from a long and detailed syllabus enforced by an authority outside of the school.

Perhaps the best statement of the fundamental fallacy of this strife for uniformity is that given by Professor Dewey in the pamphlet mentioned above (page 16), when he says:

I know of no more demoralizing doctrine—when taken literally—than the assertion of some of the opponents of interest that *after* subject-matter has been selected, *then* the teacher should make it interesting. This combines in itself two thorough-going errors. On one side, it makes the selection of subject-matter a matter quite independent of the question of interest—and thus of the child's own native urgencies and needs; and further it reduces method in teaching to more or less external and artificial devices for dressing up the unrelated material so that it will get some hold upon attention. In reality, the principle of "making things interesting" means that subjects shall be selected in relation to the child's present

experience, powers and needs; and that (in case he does not perceive or appreciate this relevancy) the teacher shall present the new material in such a way as to enable the child to appreciate its bearings, its relationships, its necessity for him.

This quotation also makes clear why those who believe in extended and detailed syllabi can think of interest only as synonymous with amusement, so that they strive for a supposed discipline which Professor Dewey shows to be subversive of true discipline as follows:³

The absurdity of much of the current conception of discipline is that it supposes (1) that unrelated difficulties, tasks that are only and merely tasks, problems that are made up to be problems, give rise to educative effort, or direction of energy; and (2) that power exists and can be trained at large apart from its application.

This first obstacle of administrative systems was considered at length at the recent meeting (February, 1909) of the Department of Superintendence of the National Educational Association by Superintendents Stratton D. Brooks, of Boston; C. E. Chadsey, of Denver; W. E. Chancellor, of South Norwalk; C. P. Cary, of Wisconsin, and R. J. Aley, of Indiana. There was a striking unanimity in their recognition of the injurious nature of present practises. All made constructive suggestions for improvement, and those who are interested in this matter should read their papers, which will be published soon in the proceedings. You should also read the able papers on this topic by Professor J. M. Coulter in the *School Review* for February, and by Professor F. N. Scott in the same journal for January. The Carnegie Foundation for the Advancement of Teaching is devoting considerable attention to this matter, and several state legislatures are considering bills relative to it.

The second obstacle—that of the lack of understanding among teachers of certain terms—is being rapidly removed by the

discussions now being held at meetings of teachers' associations and at conferences like this. I am sure we shall soon come to understand each other better, provided all can recognize that the discussion is a wholly impersonal one, carried on solely in the interests of the coming generations. We may therefore pass on to the more definite specification of the real educational problems that now confront the physics teachers.

The first important problem is that of the preparation of the child for science. There is at the present time practically no science in the elementary schools. In the earlier years of the high schools there is very much less science than there should be. Suitable courses in elementary science must be devised for and presented in the earlier years of the elementary schools, in order to store the child's mind with an adequate supply of concrete experience with the materials of science. In solving this part of their problem, physics teachers will have to cooperate with the nature study and the industrial education movements, since it is through these that the elementary basis will be laid. This is the most important and difficult problem. When it is solved, the nature of the high-school course will in large measure be determined; not, as at present, by what may come after, but by what has gone before. The college courses in turn will have been modified to fit the high-school courses, and not the reverse.

The solution of this problem will require much time and a large amount of scientific experiment. In the meantime, we can do much to make the present one-year course in the high school much more efficient than it is in yielding clear and definite concepts and in training in clear thinking. How may this be done?

The chief reason for the present failure

³L. c., p. 32.

of the physics course to train in scientific thinking seems to me to lie in the fact that the method of presentation used is thoroughly unscientific. Abstract and difficult concepts in the form of definitions and laws are thrust upon the student without warning, and before his mind is adequately prepared for them by suitable common sense discussions of his concrete experiences—he does not feel their necessity or see their use.

Illustrations of this failing may be taken from any chapter of any of the texts now in use. Thus, the discussion of light is generally introduced by statements concerning the luminiferous ether; properties of matter are introduced in terms of molecules and atoms; heat is explained as a form of energy before its properties are studied. But the most notorious offenses against the scientific spirit of the student are committed in the name of the absolute system of units; they cluster about that tiny and apparently inoffensive thing, the dyne. Unless a student gets a clear conception of what a dyne is, he is lost; because most of mechanics depends on it, in the present method of presenting the subject. Far be it from me to attempt to belittle the dyne—it is little enough already. Nor would I give the impression that the dyne is unessential for the adult physicist, or that the absolute units are not the most beautiful and useful of all the “absolutes” under which the rationalistic mind has sought to hide its real ignorance of reality. The trouble with the dyne in elementary teaching is that it can not be derived directly from experience. It depends for its definition on a convention that can not be verified by experience. The student can, of course, learn to recite the definition of the dyne, or even to write the formula that expresses this definition; and, by mechanical substitution in this formula, he may be able to solve abstract problems—prob-

lems that are made up to be problems, but that can not be realized in practise or related to experience. He can not visualize the dyne, nor form a concrete image of it—an image that is derived directly from experience and that is therefore usable in clear thinking.

To a beginner pushes and pulls are the real forces. He can appreciate their measurement by elastic springs, and their comparison in terms of pounds or grams weight. He can not, as a rule, appreciate the measurement of force in terms of mass-acceleration for three reasons, namely: (1) He has no clear scientific concept of mass and it takes considerable time to acquire it. How many of us teachers would agree on any one attempted definition of mass? (2) He has very imperfect notions of acceleration; and he really can not get a concrete, quantitative picture of this without the calculus. Did not Newton himself invent the calculus before he was able to treat acceleration? (3) In all of his actual experiences with natural phenomena the force balanced by mass-acceleration is small compared with the force balanced by friction and other resistances.

For these reasons it seems to me perfectly clear that the dyne should not be introduced at the beginning of a course in elementary physics. If a second year of work in this subject is given in the high school, the dyne might be introduced then, provided that the first course had been of the right sort; otherwise it must be left for the colleges.

Since the dyne is the actual point of contact—I might appropriately say the mathematical point of contact—between the two opposing pedagogical creeds of physicists, it is very important that we see the point clearly and appreciate its great significance for physics teaching. I, therefore, will adduce some of the arguments that are put forth in favor of retaining the dyne so as

to point out again the psychological fallacy involved. The dyne has been defended in a recent discussion before the Eastern Association of Physics Teachers,⁴ as follows:

First it will be noticed that, as the units of the system are logically derived from the fundamental units, logical reasoning on the part of the pupils will be required. Those educators who contend that the chief work of the physics teacher is to entertain and amuse will not accept this as an argument. Others, however, will take delight in the opportunity afforded for rapid-fire drill and review. Question—What is a watt? Answer—A watt is a unit of power and is equal to a joule a second. Q.—What is a joule? A.—A joule is a unit of work and is equal to ten million ergs. Q.—What is an erg? A.—An erg is the C.G.S. unit of work and is the work done by a force of one dyne acting through one centimeter. These questions can be continued until the pupil has not only shown that he knows the definition of the centimeter, the second and the gram mass, but also that he has a knowledge of what work, force, etc., themselves are.

In reply to this let me point out that reasoning with words which have no concrete content is useless and scholastic. A student may jingle along words like watt, joule, erg, dyne; but, without clear concepts of the meanings of these terms, his logical faculties get no more training than if he were arguing how many devils can dance on the point of a needle. As Mr. H. Poincaré has pointed out ("Essay on the General Definitions of Mathematics"):

What has been gained in rigor has been lost in objectivity. It is by withdrawing from reality that this perfect purity has been acquired. Demonstrations are constructed by logic, but inventions are made through intuition. To know how to criticize is good; but to know how to create is better. Logic tells us that on such and such a path we are sure to meet no obstacles; but it does not tell us which path leads to the goal. The faculty that enables us to do this is intuition.

Second: I know of no physics teachers who think the work of the physics teacher is to amuse; unless possibly it be those who

⁴ Report of the fifty-second meeting of the E. A. P. T., p. 13.

keep their students loafing over quantitative experiments from which the difficulties have been removed, by logic or otherwise, and which are therefore incapable of giving "discipline" in the true sense defined above.

Third: The string of questions and answers runs along very smoothly on paper—almost as smoothly as *The House that Jack Built*: This is the dog, that worried the cat, that killed the rat, that ate the malt, that lay in the house that Jack built. To my thinking, this latter is far richer in thought content to the student than is the string about watts, joules, ergs. Such a string of questions may surely be continued till the student has learned the words that are supposed to define the gram mass, but no amount of questioning of this sort will ever lead him to a scientific concept of mass, or to a "knowledge of what work, force, etc., themselves are." Physicists are agreed that knowledge of this sort is useless, even if it were attainable. Thus Poincaré says ("Science and Hypothesis," page 78):

Even though direct intuition made known to us the real nature of force in itself, it would be insufficient as a foundation for mechanics; it would besides be wholly useless. What is of importance is not to know what force is, but to know how to measure it.

Again (page 73):

When we say force is the cause of motion, we talk metaphysics, and this definition, if one were content with it, would be absolutely sterile. For a definition to be of any use, it must teach us to measure force; moreover that suffices; it is not at all necessary that it teach us what force is in itself, nor whether it is the cause of the effect of motion.

In like vein William James says:⁵

The term "energy" doesn't even pretend to stand for anything "objective." It is only a way of measuring the surface of phenomena so as to string their changes on a simple formula.

At this same meeting of the Eastern Association of Physics Teachers the present es-

⁵ "Pragmatism," p. 216.

entially rationalistic system was further defended as follows:

Second—It will be observed that the absolute system enables us to define in a simple manner certain physical quantities which can not otherwise be defined without great circumlocution. For example—an unbalanced force always produces some kind of acceleration. How can force be better defined than by the acceleration which it will produce? This being the case, what better unit of force can be employed than one which will give a unit mass a unit acceleration? $F=ma$ is the simplest possible statement of the measure of a force and one which, if the pupil understands acceleration, will greatly assist him in obtaining some conception of force.

To the first of these statements I will let Professor John Perry, the leader of the reform movement in England, answer:*

There is too much hankering after a kind of logical perfection which is impossible in the teaching of the average boy. I am afraid that what seems to you simple is to him complex, and what seems to you complex is to him quite simple. As a result, you have not made his studies as interesting to him as you might, and whatever is uninteresting to him is uneducational.

I may add that clear definitions grow out of experience, and by teaching word definitions that have not been justified in advance by experience, we are but training in the habit of hiding our ignorance of things under high-sounding words.

To the second statement about the simplicity of the definition of force I would remark: "Certainly." But I would place the emphasis where the writer did not intend it, namely, on the clause "If the pupil understands acceleration." I must also add: "and if he has a concrete and scientific concept of mass."

It was in addition urged that by teaching the absolute units the physics teacher has an opportunity to do a real service to the college. It would be a real service to the college if the secondary school teachers would send to the colleges young men and women with clear and definite concepts and

with a training in habits of scientific thinking, rather than with memories crammed with words and verbal definitions. That the secondary schools are not doing this real service under the present system of "absolute" teaching, is shown by the fact that 70 per cent. of the candidates in physics fail in the written examination of the college entrance board. And how about the 90 per cent. of the high-school pupils who do not go to college? Are the secondary schools doing a "real service" to them in launching them on life with a fullness of word definitions and an emptiness of definite and useful information concerning the physical world about them?

I can not help wondering how long the absolute physics will be defended on the grounds that it gives "mental discipline," that it pleases the colleges, and that it furnishes data needed by the expert physicist. Even if these claims were true, that defense has been torn to shreds in the battle over Latin; which was claimed to give "mental discipline," to please the colleges, and to furnish data needed by the professional theologian. There is certainly something in physical science for everybody, and it is equally certain that that something is not to be gained from any catechism of questions on watts, joules, ergs, dynes, etc.

Although I am convinced myself, after having tried the experiment, that the elementary physics should not attempt to teach the absolute units, I would not for an instant advocate any system of regulations by which the use of these units was prohibited. There are many able and sincere teachers who honestly believe in their use, and such teachers should not be prevented from using them. On the other hand, those who do not believe in them, who have found by their experiences that it is useless to try to teach them to their pupils, should not be compelled to do so by regulations aimed at securing uniformity and enforced by an

* *Mathematical Gazette*, January, 1909, p. 7.

authority outside the school. This is an excellent example of the way in which such regulations effectively block progress by prohibiting the teacher who would study education scientifically from trying experiments, thus dwarfing him as a science teacher by barring him from applying scientific methods to the study of his teaching problem. Until differences of this sort have been settled by experiment, it is irrational and very injurious to the students to make regulations that decide such questions in advance on *a priori* grounds.

This deductive, logical, abstract, defining-without-concept habit in present physics teaching has been inherited direct from Newton. It is a habit of which Professor Perry says:¹

I take it that the method of study into which Newton was forced, became, because of Newton, the favorite English mathematical study, and we know that it kept English mathematicians back for a hundred years. In the shape of elementary deductive geometry, it is keeping back every schoolboy now.

What does this mean? You recall that Newton, when he presented some of his optical discoveries to the Royal Society in 1672, was attacked by Hooke and others and drawn into quite a controversy. This was very distasteful to Newton; and so, before presenting his "*Principia*," he put it into such form that it would be unassailable. Euclid being the model of such necessary reasoning, this was his model. So we find that the "*Principia*" begins with definitions, axioms, scholia and the other paraphernalia of geometry. But it is very clear that Newton did not reach his definitions in any such way. They gradually developed in his mind as the result of long pondering over the phenomena, the experiments, and the known data of mechanics. Any one of you who has seriously tried to grasp the real meaning of his justly celebrated "*laws or axioms of motion*," or

¹ *Mathematical Gazette*, January, 1909, p. 5.

who has read and pondered over the voluminous literature that has been written about them, can not fail to be impressed with the mighty genius of the man who first formulated them. It was a very great feat of the scientific imagination. And yet we expect the average high-school pupil to repeat that feat in three or four lessons, and to have facility in the solution of abstract problems involving these definitions in less than a year! And this without having given him the full experimental basis for those laws nor having taught him to ponder scientifically so that he can follow the reasoning by which Newton reached his conclusions.

I have already shown that in England this fallacy of logical perfection in elementary physics has been exposed at the hands of Professor Perry. In Germany the same is true. That celebrated commission that has been studying this matter there adopted as one of its theses with regard to physics the following: "*In teaching, physics must not be treated as a mathematical science, but as a natural science.*" The meaning of this is given in the following words:

The specific value of the teaching of physics for general culture has long been diminished because of the fact that physics is treated primarily as a mathematical science. The chief reason for this is that physics itself has long regarded it as an ideal to present itself in deductive form after the manner of a mathematical system. This is particularly true of the fundamental portion of physics, the mechanics, the construction of which on a few axioms has been regarded as its chief excellence.

I am glad to be able to say that the latest and best of the German elementary texts—that of Poske—does not contain Newton's second law of motion or the absolute system. Professor Poske is editor of the *Journal for Physics Teaching*, a member of the celebrated commission and a teacher of long experience. The book is written for classes that correspond to those

in the second and third years of our high schools. The book has been received with great approbation by the German teachers. Thus although we are ahead of our colleagues across the water in the matter of laboratory equipment, they are, in my opinion, far ahead of us in their knowledge and practise of sound pedagogy.

The essential distinction that I have been endeavoring to make plain between vigor and rigor, between intuition and logic, between concrete and abstract, between relative and absolute, between interest with true discipline and duty with martial rule, has been pointed out for mechanics most clearly by Professor Henri Poincaré in his "Science and Hypothesis,"¹⁸ as follows:

The principles of mechanics, then, present themselves to us under two different aspects. On the one hand, they are truths founded on experiment and approximately verified so far as concerns almost isolated systems. On the other hand, they are postulates applicable to the totality of the universe and regarded as rigorously true. If these postulates possess a generality and a certainty which are lacking to the experimental verities whence they are drawn, this is because they reduce in the last analysis to a mere convention which we have the right to make, because we are certain beforehand that no experiment can contradict it. This convention, however, is not absolutely arbitrary; it does not spring from our caprice; we adopt it because certain experiments have shown us that it would be convenient. Thus is explained how experiment can make the principles of mechanics, and yet why it can not overturn them.

Hence the particular part of the physics teacher's problem now before us reduces to this: The present system of teaching physics in its elementary stages fails because of its leaning toward rigor, logic, the abstract, the absolute and martial law: the problem is to change the methods of teaching so that vigor, intuition, the concrete, the relative and true discipline shall prevail. One suggestion has already been made as to ways of doing this, namely,

¹⁸ English translation, p. 98.

omit the absolute units. In closing let me throw out two further hints that may assist those who wish to take part in the house-cleaning that is at hand.

Physics is suffering from lack of unity in the way it is presented to beginners. This may be remedied by a suitable use of the idea of energy. In a recent address at the University of Chicago, Professor G. H. Mead showed that the doctrine of energy plays in physical science the same rôle as does the doctrine of evolution in biological science, since it furnishes concepts and a terminology in which all forms of physical phenomena may be expressed. This terminology and these concepts are particularly useful, because they are derived from the idea of mechanical work, which is one of the most immediate and familiar of the concepts drawn from daily experiences. Most commercial accounts are ultimately balanced in terms of work or energy.

In using the idea of energy as a solvent for unifying and organizing instruction in physics it is not in the least necessary to become an "Energetiker," to deny the existence of everything but energy, and to rule out the imagination and speculation concerning atoms and the like. The idea is one easily grasped by any one, since it is drawn from such universal experience. It can be visualized in the lifting of heavy objects so as to be made very concrete. In my opinion this idea offers a fruitful field for experimentation in the teaching of the elements of physics.

Another fruitful suggestion has been made by Dr. Northrup in the *Journal of the Franklin Institute* for March, 1908. It is to use analogy—not poetic analogy, but strict analogy, such as exists between translatory and rotary motion. This same suggestion was made by Professor Henry Crew at the meeting of the Central Association of Science and Mathematics Teach-

ers last November. It is a suggestion well worth considering.

Has not the time now come when we physics teachers of America should begin experimenting with a purpose of trying to discover the live way of teaching our subject? Are we not now ready to right-about-face, and, instead of trying to make our concrete material abstract and mathematical—instead of trying to teach Newton's absolute time and space and motion—to try to make mathematics and the absolute concrete and real through physics? Shall we not take up the movement now being pushed so successfully by Perry and Armstrong in England, by Klein and Poske in Germany and by the brothers Poincaré in France, and push it along in free and progressive America as well? Surely the time is at hand when the work will be done. Let us therefore all lay hold and help, for better times are coming. C. R. MANN

THE UNIVERSITY OF CHICAGO

ALBERT B. PORTER

ALBERT BROWN PORTER was born at Indianapolis on March 16, 1864, and died at Chicago on April 16, 1909. He was a man of rare endowment, well known to many of the readers of this journal. Since, however, his published researches are comparatively few in number, he was by no means so widely known as his native abilities would ordinarily have made him.

His preparation for college, obtained at the Indianapolis High School, enabled him to enter Stevens Institute at the early age of fifteen. Most of the best training of this precocious lad was, however, obtained in his own home and at the hands of his own father, Albert G. Porter, who was governor of Indiana during the early eighties. From this period dates his acquisition of an almost faultless English style and the beginning of his acquaintance with tools and with the properties of matter. In 1882 he migrated to Purdue University, where he graduated B.S. in 1884.

The Richmond, Ind., High School was fortunate in securing the services of this modest, scholarly and skillful young man during the seven years immediately following his graduation. More than one of his students have testified to his inspiring influence and to the manner in which he helped rapidly to upbuild this institution.

In 1891 he went to Baltimore to pursue, under Rowland, Franklin and Newcomb, the subject of physics to which from earliest boyhood he had been devoted. His fellow students still recall that judicial, alert and independent attitude of mind displayed by him regarding all subjects. Pure science being his ruling passion, the atmosphere of Johns Hopkins University was more congenial to him than any other which he subsequently found.

It was during this period that he was married to Miss Therese Study, whom he had first learned to know as a student in the Richmond High School.

In 1894 he accepted appointment to the chair of physics in the then recently founded Armour Institute. It seems almost needless to add that the department was at once placed upon a high plane. His lectures were beautifully illustrated with many novel experiments and were always set forth in that clear English which can result only from clear thinking. Characteristic of the man is a summer spent with Mr. O. L. Petitdidier in learning the technique of lens grinding, figuring and polishing. After eight years' experience in teaching technical students he resigned in order to take up the manufacture and importation of high-grade physical apparatus, operating under the name of "The Scientific Shop." But we must not imagine that Professor Porter ceased to teach when he entered upon the commercial side of his work. On the contrary, his clientele became larger and more advanced, being composed mainly of instructors in physics from all parts of the country; for, being a man of cultivated curiosity and lucid expression, he had satisfaction not only in gathering information, but also in freely imparting knowledge.

His published papers relate chiefly to the diffraction theory of microscopic vision and

to other optical questions. The various circulars which issued from the The Scientific Shop were always his own, and those who have had the pleasure of reading them will recognize that they are unique in accurate scholarship, in instructiveness and in absolute candor.

No account, however brief, of Mr. Porter's work would be fair, not to say adequate, which did not include some reference to his several large volumes of manuscript "notes," in which he was in the habit of recording new ideas and experimental results. A single citation which will serve to illustrate the cleverness, ingenuity and skill of the man may also be of value to makers of lenses. It is a note, referring to an extension of the benefits of the bifocal lens invented by Benjamin Franklin and having interest as being the last problem upon which he was engaged, and is as follows:

MULTIFOCAL SPECTACLE LENS

Intended to replace the bifocal lens. Would have two advantages (1) "invisibility" in the sense of not being evidently different from a single focus lens and (2) the multifocal property should give clear vision at any distance from (say) 10 inches to infinity.

One face of the lens is curved only in the horizontal plane and the other only in the vertical plane, the radii of each surface growing shorter from top to bottom of the lens in about the same ratio. Thus one surface may be a circular cone and the other a spiral cylinder. The curvatures need not increase uniformly from top to bottom, but the increase should be at the same rate on each side so as not to introduce cylindrical error. Vertical or horizontal astigmatism can be corrected by making one surface of uniformly greater curvature than the other. The surface may be

mechanically ground and polished by simple mechanism. Angular astigmatism can possibly be corrected by a superposition of curves, but the surface would not then be "ruled," and the polishing operation might be less certain.

The fault of the lens is that the curvatures and foci are different at top and bottom of the eye. This difference is, however, slight in a large lens, and unless presbyopia is great may not be enough to cause inconvenience.

A. B. P.

August 17, 1907

Under date of January 24, 1900, occurs a two-page note describing in detail a method by which the grinding tools for such a multifocal lens may be made. Then the following:

MULTIFOCAL LENSES

Could be made with spherical surfaces by using a glass varying in density (refractive index) from top to bottom. Such a glass could be made by using a flat melting pot heated from above (to avoid convection currents) in which was placed in very thin layers the varying materials needed to give the varying density. A "guard ring" should be put in the center of the melting pot to avoid convection currents due to unequal heating or cooling around the sides of the pot. The glass should be kept in a molten condition long enough for diffusion to make the density gradient uniform, and the heat should be turned off so slowly that the top always remains hotter than the bottom to avoid convection.

A. B. P.

February 5, 1909

Hundreds of suggestive "notes" of this type lead one to wish that it might have been possible for a mind so fertile in resources to have devoted its energies to investigation and pure science, unhampered by the daily routine of teaching or commerce.

HENRY CREW

BANQUET IN HONOR OF PROFESSOR BESSEY

THE Botanical Seminar of the University of Nebraska gave on June 5 an anniversary banquet in honor of Charles Edwin Bessey, to celebrate the twenty-fifth anniversary of his professorship in Nebraska, preceded by fourteen years of professorial service at the Iowa Agricultural College. Dr. Roscoe Pound pre-

sided and first introduced Governor A. C. Shallenberger, who spoke on "Twenty-five Years for the State"; other toasts were as follows: "Forty Years for Botany," by Professor Frederic E. Clements; "His Influence as a Teacher," by Dean Henry B. Ward; "What he has done for the University," by Professor George E. Condra, and "His Influence upon the Layman," by Regent George Coupland. There was then presented to Professor Bessey a set of twenty-four volumes containing the publications of his former students.

The *Sunday State Journal* contains the following editorial appreciation: "The honors paid to Dr. Charles E. Bessey last night by the Botanical seminar of the University of Nebraska were richly deserved. Dr. Bessey has just completed forty years of active service as a teacher of botany—fifteen years at Ames and twenty-five years at Lincoln. When it is remembered that during each one of the forty years he has been in close personal contact with hundreds of young people, has fired them with his enthusiasm as a scientist and has influenced them with his beautiful and simple character—when all this is understood, the value of his career to the public becomes deeply impressive. It has been a source of pride and joy to the university that a man of international fame should decline flattering offers and large salaries to go elsewhere and should devote himself with unflagging zeal to the study of botany here in Nebraska. To the words of appreciation spoken last night the whole state joins in proud and spontaneous applause."

BRITISH ASSOCIATION TRIP TO ALASKA

A NUMBER of members of the British Association having written expressing their desire to go up the coast, arrangements have been made as below. It is desirable for members who wish to take this delightful trip to go before the association meets at Winnipeg, as the weather is often damp and the views obscured by mists during the latter part of September. Some of the members are coming through Asia, and others through Canada and the States before the meeting at Winnipeg, but as the times of arrival of those parties vary, it

has been found advisable to encourage them to travel in weekly companies, leaving Victoria at 11 P.M. on Fridays or Vancouver at 11 P.M. on Saturdays between July 16 and August 13 and again on September 10 for each of the undermentioned coast tours by the C. P. R. steamships, which also leave Seattle one day earlier than the above dates at the same through fares.

a. To Prince Rupert, Juneau (Great Gold Mine), Taku and other large glaciers, Skagway, and thence back to Vancouver in nine days, or to Victoria in ten days, traveling nearly 2,000 miles through enchanting scenery along sheltered "fjords." Cost, including meals and berths, \$60.

b. Including the above to Skagway, thence over the wonderful scenery of the White Pass Railway and down the Yukon River to Dawson (Klondike) and back. Time, about three weeks. Cost, \$180.

Beyond the latter those who have time and desire to go through Alaska round by Nome can do so at reasonable rates. Ordinary travelers' clothing suffices, with thick boots or rubber shoes for climbing. Arrangements are being made to entertain members during their stay at Victoria.

THE CARNEGIE FOUNDATION FOR THE ADVANCEMENT OF TEACHING AND THE GEORGE WASHINGTON UNIVERSITY

THE following letter has been addressed by the president of the Carnegie Foundation for the Advancement of Teaching to the president of the George Washington University:

June 4, 1909.

PRESIDENT CHARLES W. NEEDHAM,
The George Washington University,
Washington, D. C.

Dear Sir:—I am directed by the executive committee of the Carnegie Foundation for the Advancement of Teaching to send to you as president of the George Washington University the following communication.

The George Washington University reported to the Foundation a productive endowment of \$219,832.98 as of date August 21, 1907. In the financial statement submitted some time since it reported as of date October 3, 1908, a productive endowment of \$123,500.

The rules of the Carnegie Foundation require that an institution, to be entitled to the privileges of the retiring allowance system, must have

a productive endowment of not less than \$200,000. This proviso was made because experience has proved that no college can maintain fair educational standards without adequate endowment.

The examination which I have just caused to be made of the George Washington University shows that its announced standards of admission to the various schools are not enforced.

In the college division of the University regular students are admitted with reasonable regard to the stated admission requirements, but of the total enrollment more than one third are special students. The value of the A.B. degree, however, is seriously lowered by the lax administration of the College of Political Sciences and the Division of Education, to which admission is granted with little regard to the published entrance requirements. The Law School announces a four-year high-school education as a prerequisite for admission, but does not enforce it. Similarly in the Medical School the announced requirements for admission have been repeatedly evaded. If the entrance requirements to this school were actually enforced, the enrollment would be so greatly reduced that the department could not continue: a result, I may add, entirely in the interest of medical education, since the District of Columbia and the region about it are over-supplied not only with physicians, but with weak medical schools.

The executive committee feels compelled also to protest against the extraordinary action of the institution in forcibly retiring two professors, both of whom are in the prime of their active teaching, on the ground that the institution needs to save money by the retiring allowance system, but it is entirely contrary to the spirit in which this Foundation was conceived and is a blow at academic dignity and academic freedom.

The committee further calls your attention to the extract from the rules for the admission of institutions, "The Trustees of the Carnegie Foundation for the Advancement of Teaching reserve the right to discontinue the privilege of participation in the system of retiring allowances of the Foundation whenever, in the judgment of the trustees, an institution ceases to conform to the regulations maintained by the trustees. Such withdrawal shall not, however, result in the discontinuance of retiring allowance already granted."

The executive committee, by virtue of the authority conferred upon it under the by-laws, in view of the conditions existing in the George Washington University referred to above, conditions which are entirely out of harmony with the

educational ideals for which the Foundation stands, informs you with great regret that the relation of the George Washington University as an accepted institution is terminated with this date.

Very truly yours,

(Signed) HENRY S. PRITCHETT,
President

SCIENTIFIC NOTES AND NEWS

At its last meeting the Rumford committee of the American Academy of Arts and Sciences voted a grant of \$300 to Professor W. W. Campbell, of the Lick Observatory, for the purchase of certain parts of a quartz spectrograph and to Professor M. A. Rosanoff, of Clark University, a grant of \$200 in further aid of his research on "The Fractional Distillation of Binary Mixtures."

MR. JOHN J. CARTY, chief engineer of the New York Telephone Company, has received from the Emperor of Japan the decoration of the Order of the Rising Sun in recognition of engineering services rendered to Japan.

THE Bessemer medal of the British Iron and Steel Institute has been presented to M. A. Pourcel.

PROFESSORS YVES DELAGE and M. G. Retzius have been elected foreign members of the Linnean Society.

MR. HORACE DARWIN, F.R.S., has been elected a corresponding member of the Vienna Academy of Sciences.

MR. CLARENCE J. HUMPHREY, assistant in botany in Cornell University, has accepted a position as scientific assistant in forest pathology in the Bureau of Plant Industry.

THE Bowdoin prizes for essays in English for the academic year 1908-9 have been awarded by the faculty of arts and sciences of Harvard University. Three prizes of \$200 each were awarded to graduates. The first of these went to C. L. B. Shuddemagen for his essay on "Mechanical Analogues for Electromagnetic Systems." R. C. Mullenix, the second of the graduate prize winners, had as his subject, "The Neurone Theory; Its Development and Its Present Status."

PROFESSOR JOSEPH P. IDDINGS, of the United States Geological Survey, who has been occu-

pied during the past year in the preparation of a work on igneous rocks, the first volume of which has just been published by John Wiley and Sons, has severed his connection with the University of Chicago, and has started on a visit to portions of Japan, China, the Philippines and Java, under the immediate auspices of the Smithsonian Institution of Washington. The purpose of his visit is the study of the volcanic rocks of these regions in order to complete the second volume, or descriptive part, of his book. Publications may be sent to him in care of the Smithsonian Institution in Washington.

FREDERICK MONSEN has gone to the deserts of Chihuahua and Sonora to make ethnological research among the Indians of those parts and to study the physical geography of the region. Late in July, Mr. Monsen will visit Arizona, where three months will be devoted to investigation among the Hopi and Navajo Indians, after which he will endeavor to photograph the Grand Canyon from above by means of kites which he will fly from the rim of the canyon, sending them over 6,000 feet above the surface of the river. Mr. Monsen returns to New York next November.

MR. WILLIAM B. RICHARDSON, collecting for the American Museum of Natural History in Nicaragua, announces the shipment of a large collection of birds and mammals made during the last six months at points ranging in altitudes from 700 to 5,000 feet.

ALBERT A. GIESECKE, Ph.D. (Cornell), has been commissioned by the Peruvian government to organize a system of commercial and technical education in Peru, and will leave in a short time for Lima.

PROFESSOR KENGO MAKINO, of the department of electrical engineering, University of Waseda, Tokyo, Japan, is now on his way home *via* Europe after a couple of years spent at Cornell in post-graduate study.

DR. GEORGE DOCK, of New Orleans, has sailed for England and the continent. He will attend the International Medical Congress at Buda-Pesth.

DR. ALFRED DACHNOWSKI, of the botanical department of the Ohio State University, is

spending the summer in Europe. He will visit the Azores, Italy, Switzerland and Germany, and will make observations on forestry, as practised in those countries.

RECENT visitors at the Bureau of Plant Industry of the U. S. Department of Agriculture have been Mr. B. Barlow, of the Ontario Experiment Station; Mr. W. Henry Grant, secretary of the Canton Christian College, Canton, China; Mr. Osborn Ashton, of Cairo, Egypt; Mr. Horace G. Knowles, formerly minister to Roumania; Dr. Arthur Donaldson Smith, Consul at Patras, Greece.

At the University of Pennsylvania the address before Phi Beta Kappa and Sigma Xi will be given by Professor H. C. Richards, of the department of physics.

PROFESSOR CHARLES S. PROSSER has given a course of lectures at Ohio State University describing the opportunities for graduate study in geology at some of the leading American universities. Those to which the greatest attention has been given are Johns Hopkins, Princeton, Columbia, Yale, Harvard, Cornell and Chicago.

MR. JOHN HAYS HAMMOND gave the address at the thirty-fifth annual commencement of the Colorado School of Mines, held on May 28.

THE Croonian lecture of the Royal Society was delivered on June 10, by Professor E. A. Schäfer, F.R.S., on "The Functions of the Pituitary Body."

THE statue of Lamarck, erected by international subscription, was unveiled in the Jardin des Plantes, Paris, on June 18.

MR. CHARLES L. BUCKINGHAM, well known as an inventor in the field of telegraphy and as a patent lawyer, died at this home in New York City on May 31, at the age of fifty-seven years.

THE death of Dr. J. D. E. Schmeltz, director of the State Museum of Ethnography at Leyden, Holland, is announced. He began his work in the Godefroy Museum in Hamburg, whence he was called to Leyden in 1884 as assistant of Dr. Serrurier. Later on he became director of the museum, and the development of the collections during the last twenty

years has been due to his untiring energies. He was the founder and editor of the "International Archives of Ethnography."

Mr. THOMAS MELLARD READE, known for his contributions to geology, has died at his home in Liverpool, at the age of seventy-seven years.

The death is also announced of M. Eugene Grenet, the French electrical engineer.

DURING the present school year, the council of Phi Lambda Upsilon, a national honorary chemical society, has granted three charters: the first, in Chicago, as the Chicago Alumni Chapter; the second, in New York City, as the Columbia University Chapter, and the third, in Ann Arbor as the University of Michigan Chapter. The society was founded at the University of Illinois in 1899. It has for its fundamental object the promotion and protection of high scholarship and original investigation in all branches of pure and applied chemistry. Active membership is limited to graduate and advanced undergraduate students, except in the case of the student having the highest average grade at the end of the sophomore year. The election of men is based primarily upon their scholastic standing and promise of research ability. Among the honorary members of the society there are: Professors W. A. Noyes, C. F. Chandler, S. L. Bigelow, Louis Kahlenberg, H. C. Sherman, E. D. Campbell, S. W. Parr, M. T. Bogert, H. S. Girdley, S. M. Babcock, R. H. Chittenden, C. G. Hopkins, A. P. Matthews, Drs. L. W. Andrews, A. G. Manns and T. J. Bryan.

At the annual meeting of the Society of Detroit Chemists, held May 28, the following officers were elected: *President*, Frank T. F. Stephenson, chemistry department, Detroit College of Medicine; *Vice-president*, L. D. Vorce, Pennsylvania Salt Manufacturing Company; *Secretary*, H. C. Hamilton, Parke, Davis & Company; *Treasurer*, W. D. Mainwaring, Railway Steel Spring Company. The membership reported is 84. Regular monthly meetings were held through the year, with attendance about 50 per meeting. Preparations have been practically completed for the entertainment of the American Chemical Society in June.

THE Biological Club of Oberlin College was organized during the last year, its membership embracing the instructors in the departments of botany, geology, physiology and zoology. Its officers are: *President*, Professor E. B. Branson; *Secretary*, Professor R. A. Budington. During the year the following meetings have been held:

November 25—"Dinichthid Fishes of Ohio, with special reference to a species of *Dinichthys* in the Oberlin Museum," by Professor E. B. Branson.

December 9—"Internal Secretions," by Professor R. A. Budington.

January 13—Reports by members who attended the Association meetings in Baltimore during the Christmas holidays.

January 27—"Present-day Conceptions as to the Role of the Sympathetic Nervous System in Man," by Professor F. E. Leonard.

February 10—"Some Nuclear Phenomena in the Fungi," by Dr. Susan P. Nichols.

February 24—"Some Recent Work on the Protozoa," by Professor M. M. Metcalf.

March 10—"Feeding Experiments with Birds," by Professor Lynds Jones.

March 25—"Maturation Phenomena in Plants and Animals," by Professor F. O. Grover.

April 14—"The Ecological Succession of Birds," by Mr. B. R. Showalter.

April 28—"The Planetesimal Hypothesis," by Professor E. B. Branson.

May 12—"The Phylogeny of the Angiosperms," by Mr. C. B. Wilson.

May 28—"The Static vs. the Dynamic and Vitalistic Theories of Evolution," by Professor F. O. Grover.

In connection with the annual grant voted by Parliament in aid of scientific investigations concerning the causes and processes of disease, Mr. Burns, the president of the Local Government Board, has, as we learn from *Nature*, authorized the following special researches: (1) a continuation of the investigation into protracted and recurrent infection in enteric fever, by Dr. T. Thomson, in conjunction with Dr. Hedingham; (2) a continuation of the investigation into protracted and recurrent infection in diphtheria, by Dr. T. Thomson and Dr. C. J. Thomas; (3) a continuation of the investigation into flies as carriers of infection, by Dr. Monckton Cope-

man and Professor Nuttall; (4) a continuation of Dr. Andrewes's investigation on the presence of sewage bacteria in sewer air, with the view of ascertaining their number and the distance they can be carried by air currents; also a continuation of Dr. Andrewes's investigation into the part played by changes in bone marrow in the defensive mechanism of the body against infection; (5) a continuation of Dr. Savage's investigations on the bacterial measurement of milk pollution, and on the presence of the Gaertner group of bacilli in prepared meats and allied foods; (6) an investigation into the chemical and physical changes undergone by milk as the result of infection by bacteria, and into the relation of the pancreas to epidemic diarrhoea, by Dr. Schölberg and Mr. Wallis; (7) an investigation of the records of charitable lying-in hospitals as to the nutrition of the mother and other factors influencing the vitality of infants and their progress in the first fourteen days of life, by Dr. Darwall Smith; (8) an investigation into the occurrence and importance, in relation to treatment, of mixed infections in pulmonary tuberculosis, by Dr. Inman; (9) an investigation on the relative importance of certain types of body-cells in defense against the tubercle bacillus, and the effect of tuberculin and other remedial agents on their activities, by Dr. J. Miller.

At the recent conversazione of the Royal Society, Dr. George E. Hale, who has recently been elected a foreign member of the society, exhibited photographs illustrative of work at the Mount Wilson Solar Observatory, as follows: (1) Three photographs of the sun, taken at the Mount Wilson Solar Observatory, April 30, 1908, showing: (a) the photosphere, with sun-spots and faculae; (b) the flocculi of calcium vapor; (c) the flocculi of hydrogen, at a higher level in the solar atmosphere. The hydrogen photographs, which are made with the spectroheliograph, reveal the existence of cyclonic storms or vortices associated with sun-spots. On the hypothesis that the rapid revolution of electrons in the vortices should produce a magnetic field in sun-spots, a search was made for evidences of the Zeeman effect. Doublets and triplets were found in the spot spectrum, showing all of the polarization phe-

nomena observed by Zeeman in the laboratory, and proving the existence of a magnetic field. The strength of the field (at the level of the iron vapor) ranges from 2,900 to 4,500 C.G.S. units in different spots. (2) Photograph of the sun, taken on Mount Wilson, October 7, 1908, with the red line of hydrogen. The vortices surrounding two large spots in the northern and southern hemispheres appear to rotate in opposite directions. The magnetic fields in these spots were found to be of opposite polarities, as opposite directions of rotation would require. (3) Two transparencies, showing to better advantage the hydrogen vortices in the photographs of April 30 and October 7. (4) Six photographs, showing the mounting of the 60-inch reflector of the Mount Wilson Solar Observatory and the mode of transporting the tube to the summit on a motor-truck. (5) Blue print, showing design for tower telescope, of 150 feet focal length, now under construction for use on Mount Wilson. The hollow members of the outer skeleton tower shield (without touching) the corresponding members of the inner skeleton tower from the wind. The outer tower also carries a dome to protect the heliostat and other instruments, which are supported at the summit of the inner tower. An image of the sun, 16 inches in diameter, will be formed in a laboratory (not shown) at the base of the tower. The spectrograph for studying this image will have a focal length of 75 feet, and will be mounted in a well beneath the laboratory.

THE American Ethnological Society has reprinted Volume III. of its *Transactions*, containing the important paper by William Bartram, on the "Creek and Cherokee Indians," written in 1789; and also the papers by E. G. Squier, on the "Archeology and Ethnology of Nicaragua"; by J. F. Irias, on the "Rio Wanks and the Mosco Indians"; by C. O. Copeland, on a "Choctaw Tradition"; by Berthold Seeman, on "The Aborigines of the Isthmus of Panama"; by Andrea Paey, on the "Antiquities of Cuba." The volume was never issued, almost the whole edition having been burned with the printing establishment. It is claimed that only fifty copies of the original edition were saved. The volume may

be obtained from the American Ethnological Society, Sub-Station 84, New York City.

THE department of railway engineering of the University of Illinois has recently erected a drop testing machine which is identical in design with the standard machine of the Master Car Builders' Association. This apparatus will be used in making impact tests of such materials as car couplers, wheels, axles, etc. It consists essentially of a spring-supported anvil weighing 20,000 pounds (upon which is placed the specimen to be tested), and a hammer weighing 1,640 pounds, which runs in vertical guides rising at either side of the anvil. This hammer may be dropped in these guides from any height up to 50 feet. The addition of this machine to the existing equipment of the College of Engineering of this institution renders it possible to make there tension, compression, bending and impact tests of all materials of construction, on specimens of the full size ordinarily met with in practice. Through the courtesy of Mr. A. W. Gibbs, the Pennsylvania Railroad Company furnished the drawings and loaned its patterns for the construction of this machine. The Cleveland, Cincinnati, Chicago & St. Louis Railroad Company, through its superintendent of motive power, Mr. William Garstang, has donated to the university its services in connection with the work of construction and assembling the machine, which was done at the Urbana shops of this company.

UNIVERSITY AND EDUCATIONAL NEWS

THE state legislature now in session has provided the University of Wisconsin with approximately \$2,500,000 for the next two years, beginning July 1. The permanent income of the university is supplied by a tax of two sevenths of a mill on each dollar of assessed valuation of the property of the state. This tax will yield the university approximately \$750,000 for the year 1909-10, and over \$800,000 for the year 1910-11. The sum of \$100,000 annually for the next two years was appropriated in addition to meet the needs of the growth of the institution not covered by the increase in the tax income fund. Besides this \$50,000 a year was given for books and

apparatus. The legislature also provided \$600,000 for buildings to be erected in the order of their greatest need during the next two years. This is a continuation of the building fund of \$200,000 a year for a period of three years. For extension work \$50,000 was appropriated for next year, and \$75,000 for the year following. An additional grant of \$30,000 a year was made for agricultural extension, and \$20,000 a year was provided for farmers' institutes.

MR. JOHN FRITZ, of Bethlehem, Pa., in whose honor a gold medal was founded on his eightieth birthday by the four great national engineering societies, has given \$50,000 to Lehigh University for an engineering laboratory.

DR. E. F. NICHOLS, professor of experimental physics at Columbia University, has been elected president of Dartmouth College, where he was head of the department of physics from 1898 to 1908.

AT the June meeting of the board of trustees of the University of Arkansas a college of agriculture was established. Dr. C. F. Adams, acting director of the Experiment Station, was promoted to the deanship and directorship of the college and station.

MR. ALFRED C. LANE has resigned his position as state geologist of Michigan to take effect on September 1. He will be in Houghton during most of the summer. After September 1 his address will be Tufts College, Mass.

H. E. JORDAN, Ph.D., adjunct professor of anatomy (in charge of histology and embryology) at the University of Virginia, has been promoted to the rank of associate professor.

DR. M. W. BLACKMAN (Harvard '05), of Western Reserve University, has been elected assistant professor of zoology in Syracuse University. He will succeed Mr. B. G. Smith, who has accepted the position of instructor in zoology in the University of Wisconsin.

MR. F. G. SPECK has been appointed instructor in anthropology at the University of Pennsylvania, not at the University of California, as was incorrectly stated in a recent issue of this journal.

At the commencement exercises of Lehigh University the following announcements were made: Robert W. Hall becomes lecturer on forestry as well as professor of biology; Barry MacNutt, assistant professor of physics, is made associate professor of physics; Percy Hughes, assistant professor of philosophy, psychology and education, becomes professor of philosophy and education in charge of the department; Vahan S. Babasianian, instructor in chemistry, becomes assistant professor; James Hunter Wily, instructor in physics, becomes assistant professor; R. J. Gilmore is appointed instructor in biology.

DISCUSSION AND CORRESPONDENCE.

MINIMAL QUANTITIES OF FOOD PRESERVATIVES

A CURIOUS instance of a fallacious argument cast in pseudo-mathematical form appears in the evidence of Dr. Harvey W. Wiley before the Committee on Interstate and Foreign Commerce, House of Representatives, in February, 1906. The argument is repeated in more deliberate language (identical in the three) in Bulletin 84, Part II., of the Bureau of Chemistry, of the Department of Agriculture (1906), at p. 754, in *Foods and their Adulterations* (1907) at p. 38 and in the *Proceedings of the American Philosophical Society*, Vol. 47 (1908) at p. 326. As the latter publications are readily accessible to the scientific world, I shall quote only the informal statement of the argument before the committee of the house:

This is a graphic chart showing the comparative influence of foods and preservatives (Fig. 1). Of course we have to assume the data on which this chart is constructed. You will understand that.

We will suppose that a normal dose of a drug is nothing. We do not need it at all. Now imagine that the lethal dose of a drug—that is, the dose that will kill—is 100, and then we go to work and measure at three points—at 75, at 50 and at 25. These are points at which we can measure. We can not measure up towards the right there, because the line almost coincides with the basic line, and the deviation is so slight that no method of measurement that we know of could distinguish them.

I omit here some reference to ~~the curve in the~~ diagram which appears to have ~~been~~ corrected before printing.

The lethal dose of that drug is 100. That is written up there on the left. I will just trace that. The normal dose of a drug in the case of a person in health is zero. Then if we use a little drug I can measure it here. I can measure it

FIG. 1. Graphic Chart Representing the Comparative Influences of Foods and Preservatives.—Wiley.

again here (indicating) and I can measure it again here (indicating). Now from these three points I can construct a curve and calculate the lethal dose, which we will assume to be 100. That much drug would kill; no drug would not hurt at all.

The relative injury of a drug can be calculated mathematically from a curve constructed like that on experimental data, and I could tell you mathematically, by applying the calculus there, just what the hurtful value of that drug would be at an infinitely small distance from zero. You have doubtless, all of you, studied calculus, and you know how you can integrate a vanishing function. I used to know a good deal about calculus myself, and I could, by integral calculus, tell you the injurious power of a drug at an infinitely small distance from zero—that is, an infinitely small dose.

Now see what a contrast there is between a food and a drug.

The lethal dose of a food is none at all. That kills you; you are starved to death. The normal dose is what you eat normally, 100. I starve a man, and I measure the injury which he receives

at different points. I can mathematically plot the point where he will die.

That one chart shows to this committee in a graphic form, better than any argument could, the position of a drug in a food, as compared with the food itself. They are diametrically opposite. The lethal dose of one is the normal dose of the other, and *vice versa*. Therefore the argument *de minimis* as far as harmlessness is concerned is a wholly illogical and non-mathematical argument, and can be demonstrated by calculus to be so.

The reader is urged to refer to the more formal statement in either of the other publications, and to note the confusion of thought, by virtue of which deviation from the perpendicular line is (correctly) treated as the measure of injurious effects in the case of food, but deviation from the horizontal (1) line, as the measure in the case of drugs.

The argument contains three fallacies so patent that (to adapt words employed by the witness in criticism of those who hold the opposite opinion) "it seems astonishing in these days of rigid scientific investigation that such fallacious reasoning can be seriously indulged in for the sake of proving" the *harmfulness* of minute quantities of non-condimental preservatives.

First and most important. Absolutely no evidence is offered that the curves actually have the form which is assumed for them.

Second. "Food = 0" can not be regarded as the lethal dose in the same sense that "preservative = 100" is a lethal dose.

Third. Quantity of food and injurious effects can not be measured in the *same direction* in a diagram purporting to show the relation between them.

It seems almost incredible that, repeated by the author as the argument has been over and over again during the past three years, recast in language, scanned by his assistants, none of these fallacies has been convincingly borne in upon his mind.

A lethal dose of any substance is the quantity which, administered at one time, is sufficient to cause death. To assume food = 0 a lethal dose is to assert the absurdity that food (and indeed every individual food sub-

Page 249 of the evidence.

stance) must be taken every minute of one's life. On the other hand, it is undoubtedly true that excessive quantities of food (and of individual foods) produce injurious effects. Logically, therefore, the food curve in Dr. Wiley's diagram, whether it refers to food in general or to any individual food, should—after touching the right vertical axis at "100 normal dose"—turn back to the left, and reach a true point of lethal dose at a point above 100. That is to say, it should have the general form represented by *ABC* in Fig. 2. If there be such a thing as a lethal dose of food, is it not the quantity represented by this point above 100 rather than the zero quantity? This diagram makes it clear that the cases of

FIG. 2. Possible Forms of Curves Representing Injurious Effects of Foods and of Food Preservatives.

food and preservative are not diametrically opposite, as maintained by Dr. Wiley. Evidently the principle that any substance which is injurious in any quantity is injurious in all quantities, however small, is absurd as applied to food substances. And there seems no justification for laying down any principle "*de minimis*" which shall apply solely to preservatives or to non-condimental preservatives, or

(most arbitrary limitation of all) to non-conformal preservatives not naturally present in the food.

In Fig. 2 are shown several possible forms for the preservative curve, alternate to the form given in Dr. Wiley's diagram. Two of these, *ADE* and *FGE*, represent the preservative as beneficial in small quantities and injurious in larger. The former represents the preservative as essential in some quantity; in other words, it would make the difference between food and preservative one of quantity merely, not one of kind. A curve of this kind is conceivable for a preservative such as benzoic acid or salicylic acid, both of which are normally present in minute quantities in many fruits.

The writer does not mean to assert that the curves for any preservatives have been shown to have the forms represented in Fig. 2. What he does wish to emphasize is that there is nothing in the mathematics of the case requiring them to have the form represented in Dr. Wiley's diagram, and therefore no justification for the argument that chemically preserved foods are injurious because the preservatives produce injurious effects when administered in quantities larger than would be contained in chemically preserved foods.

MACDONALD COLLEGE,
QUEBEC, CANADA

THE CHALK FORMATIONS OF NORTHEAST TEXAS

In the *American Journal of Science* for May, 1909, Article XXIX. is entitled "The Chalk Formations of Northeast Texas," by Mr. C. H. Gordon, the substance of which is to prove that the two formations of Texas, originally defined by me as the Austin chalk and the Anona chalk, are identical.

If such is the case, and I have long believed that it might be so, Mr. Gordon would do a service to science in proving the fact. I think, however, that in this paper where the author has entered into the question of record, his statements are neither complete nor accurate.

I spent many years of my life in endeavoring to define the many Cretaceous formations

of my state, and to disentangle them from previous confusion. The various conclusions thereon were progressive, and after the date of the last paper cited (1893) by Mr. Gordon as coming from me and before I retired from the subject, I learned and published much. A final work was published in which the previous results were summarized and errors corrected. Furthermore, the uncertainty as to the position of the Anona chalk was clearly stated. It certainly would seem a matter of justice for Mr. Gordon, in setting my views, to cite the latest published ones.

In the final work alluded to I clearly stated on page 341:

That the writer has considered this chalk (Anona) to represent a higher horizon than the Austin chalk, but its exact relationship is a subject of future determination.

Also on page 337 I note the difficulty "owing to the lack of (continuous) outcropping sections" of separating the Austin chalk from the Navarre formations in the Red River district.

Furthermore, in discussing the correlation south of Red River of the various members of the Upper Cretaceous in northeastern Texas, I confessed my "utter inability, notwithstanding the years of study, to correlate the various outcrops of these beds, nor can it be done by minute paleontologic research, such as he (the author) has not had opportunity to undertake," and such as Mr. Gordon confesses he has not undertaken.

Mr. Gordon does not even mention the paper above quoted, which was my last work on the Cretaceous and which is entitled "Geography and Geology of the Black and Grand Prairies, Texas, Twenty-first Annual Report of the United States Geological Survey," Washington, D. C., 1902.

So far as the writer is concerned, it is a pleasure to see other workers continue the researches in the geology of Texas, where there are hundreds of problems and details still unsolved and unrecorded, but I do think it fair that if an author endeavors to present a record of previous researches, and opinions, that they should be cited fairly. The score or

more of formation names of my own invention utilised in Mr. Gordon's article without credit, at least, attest that the studies of the Texas Cretaceous by me left some impress upon the subject.

ROBT. T. HILL

THE DAYLIGHT SAVING BILL

TO THE EDITOR OF SCIENCE: On page 453 of SCIENCE for March 19, 1909, a reference to the "Daylight Saving Bill" is introduced by the statement: "It is said that the Ohio state legislature once passed a bill establishing the value of π to accord with the views of some circle squarer."

A declaration beginning "it is said" is usually safe against correction, because anything may be "said," but in this instance I am moved to say that the laurel wreath has been put upon the wrong brow.

It was in Indiana, nearly twenty years ago, that such a bill was introduced by a member of the state legislature, but it was "laughed out of court," after making some progress in the lower house, as such measures often do where not much attention is given to the real meaning of every bill put upon the calendar. As far as I know, the legislature of the state of Ohio has not yet concerned itself with the ratio of the circumference of a circle to its diameter. After all, a good deal may be said for a state legislature that has devoted even a brief hour to an intelligent consideration of the value of π , and a careful investigation might show that the ability to do this is by no means restricted to regions east of the Allegheny Mountains. It is a well-known fact that of the Presidents of the United States serving within the last half century (barring one recently retired, who forms a class by himself), the two who were most appreciative of the work of scientific men and most capable by reason of their own knowledge and experience, of determining its value, were chosen, one from Ohio and one from Indiana, while that one least so was from the great Empire State. The record of the "middle west" in this respect is sure to be maintained during the administration just now beginning.

It is a serious mistake to put the author of the daylight saving bill in the same class with the circle squarers. The measure has been given much attention by all of the best English newspapers and periodicals during the past year and, with few exceptions, the criticisms have been most favorable. The passage of the bill has been urged by a very large number of eminent Englishmen, including many of the most distinguished men of science, and the advantages its adoption would secure are so many that it seems tolerably certain to receive the approval of parliament in the not distant future.

T. C. M.

DRESDEN, GERMANY

LIBRARY BOOK-STACKS WITHOUT DAYLIGHT

TO THE EDITOR OF SCIENCE: I was greatly interested in the short abstract of Mr. Bernard R. Green's address on "Library Book-stacks without Daylight," which appears in SCIENCE for April 9, 1909, p. 592.

I remember very well probably five or six years ago a conversation that I had with Mr. Green in connection with the new library building of the College of Physicians of Philadelphia, when I made the following suggestions, which I would like to put on record for the consideration of others.

It seemed to me that the ideal book-stack should be built with solid brick walls without any openings of any kind, and that even in the roof there should be no skylight and no openings except for the chimneys and ventilation. Artificial light could be turned on and off at will and would provide amply and inexpensively for the light. Forced ventilation would keep the air pure. This method of construction would have the following advantages:

1. A wall of solid brick is much cheaper than one with openings for windows, which must be filled with expensive wire glass, to which must be added the cost of iron shutters, with some automatic device for their closure.
2. It is a much better protection against fire.
3. It excludes all dust.
4. The book-stacks can be placed in the

stack-room at any distance; farther apart or nearer together, as required, irrespective of their relation to daylight through the windows.

5. As Mr. Green has pointed out, daylight is injurious to books.

6. The temperature of the room will be more equable, the internal heat being retained in the winter, and the external heat being excluded in the summer.

I hope, if this commends itself to architects and librarians, that some day the board of directors of a library may act upon it. The only drawback that occurs to me is that architecturally it would not be attractive in appearance, but as the book-stack is usually in the rear of the building and more or less hidden from view, I think this would not be a very serious objection.

SCIENTIFIC BOOKS

The Thirteen Books of Euclid's Elements Translated from the Text of Heiberg with Introduction and Commentary. By T. L. HEATH, C.B., Sc.D. Cambridge, University Press. 1908. Three vols.

Differential and Integral Calculus. By DANIEL A. MURRAY, Ph. D., Professor of Applied Mathematics in McGill University. New York, Longmans, Green and Co. 1908. Pp. xviii + 491.

An Elementary Treatise on the Differential Calculus Founded on the Method of Rates. By WILLIAM WOOLSEY JOHNSON, Professor of Mathematics at the United States Naval Academy, Annapolis, Maryland. New York, John Wiley and Sons. 1908. Pp. x + 191.

In these days of prolific writing when even the worst books (if indeed such a lower limit exists) must be "noticed" and the best, owing to consequent lack of space, may not be really reviewed, one is at a loss to know how properly to signalize the appearance of so important and excellent a work as this latest production from the pen of Dr. Heath. Of this work it is safe to say—and that is much—that no other better illustrates the great service of British scholarship in rendering the

ancient classics accessible and attractive to our time, and no other better illustrates the truth of Cousin's *mot: La critique est la vie de la science*. No account of the work can be bad if it has the effect of inducing the reader to procure a copy for himself, and no account can be good if it have the opposite effect. For students and teachers of mathematics or of philosophy, this edition of the "Elements" may be said to be indispensable.

It is only after examination of the volumes that one can realize how utterly impossible it is to convey in a few lines anything like an adequate conception of the riches that Dr. Heath has given us. Nevertheless, a few hints—the meagerest of indications—must be given. The introduction, which occupies more than a third of the first volume, is composed of nine chapters, entitled Euclid and the Traditions About Him, Euclid's Other Works, Greek Commentators other than Proclus, Proclus and his Sources, The Text, The Scholia, Euclid in Arabia, Principal Translations and Editions, and (ninth chapter) On the Nature of Elements, Elements Anterior to Euclid's, First Principles, etc. Of the man Euclid, as of many another great determinator of the world's career, but little is known, and the chapter on Traditions, though it furnishes nothing new, is valuable as collecting, sifting and citing the literature of the old. One of the traditions, whether or not it be true in fact, is at all events true in spirit, and will be relished by that variety of practitioner engineer who views mathematics as he views a wheelbarrow or a spade. "But what shall I get by learning these things?" said a pupil to Euclid after learning the first theorem. Thereupon Euclid called his slave and said, "Give him threepence, since he must make gain out of what he learns." The late Sylvestre, it is remembered, on being asked to state the "use" of the theory of substitution groups, on which he had been lecturing, replied, "I thank God that, so far as I know, it hasn't any." It would be interesting to know what proportion of scientific men are aware of the fact that Euclid wrote several scientific works other than the "Elements," as the hopelessly lost "Pseudaria," said by Proclus to be "by way

of cathartic and exercise," designed, that is, to aid the beginner in the discovery of paralogisms and in the discrimination of true principles from the specious and false; the still extant "Data"; the book "On Divisions (of Figures)," which though "lost in Greek," "has been discovered in the Arabic"; the three lost books of "Porisms"; the two works entitled "Surface-loci" and "Conics," both lost; the still extant "Phænomena," an astronomical work; and the "Optics," edited by Heiberg in 1895. In the two chapters (27 pages) devoted to Greek commentators upon Euclid and especially to Proclus and his Sources, Dr. Heath has given not only detailed citations of the immense body of literature bearing upon these matters, but—what is far more—a most luminous and valuable digest of it all. Then follows the chapter of 18 pages dealing with the text. Here we have an interesting account of the several celebrated manuscripts from which knowledge of the content of the "Elements" is mainly derived, a statement of the critical principles followed by Heiberg in the comparison and evaluation of the sources, and a good indication of the ingenuity, of the prodigious scholarship, labor and devotion that enabled Heiberg to produce his monumental work on Euclid. This work was published between 1883 and 1888. It is the "definitive text" contained in it that Dr. Heath has translated into English and that his scholarship has enabled him to set in the light of modern researches into the foundations of geometry. In view of the empire that Euclid has exercised in British education, it is especially interesting to learn, in the chapter on Translations and Editions, page 95, that the great Greek classic, or some portion of it at all events, found itself in English dress as early as the first half of the tenth century. In support of this contention, Dr. Heath cites the following quaint lines from "*Rara Mathematica*":

The clerk Euclide on this wyse hit fonde
Thys craft of gemetry yn Egypte londe
Yn Egypte he taughte hyt ful wide,
In dyvers londe on every ayde.
Many crys afterwarde y understonde

Yer that the craft com ynto thys londe.
Thys craft com into England, as y yow say,
In tyme of good kyng Adelstone's day.

If among the many students of recent American and English, Italian and German work in the foundations of geometry, there be any one who imagines that nearly all of the fine things presented in such work are new, there await him in the closing chapter of Dr. Heath's introduction a pleasant surprise and a happy emancipation. Indeed this chapter of 38 large octavo pages is an exceedingly valuable contribution to the historico-critical literature that pertains to the common ground of logic and mathematics. In it is set forth in clear and orderly fashion the best thought—and how fine and penetrating much of it is!—of pre-Euclidean and post-Euclidean philosophers and geometers from Plato and Aristotle down to Proclus—a period of nine centuries—the best thought, I say, of the best intellects of antiquity regarding such eternally interesting matters as the nature of scientific (and especially) geometric *elements*, of the nature and significance of *axioms* (or common notions) and *definitions*, of *hypotheses* and *postulates*, of *existence assumptions* and *existence proofs*, of *theorems* and *problems*, *lemmas*, *cases* and *porisms*, of methods of *argument* and *demonstration*, *objection*, *reduction*, *analysis* and *synthesis*. Much that has been recently written about these things is new and much of it is but repetition—repetition that is sometimes inferior in point of form and doubtless often unconscious. It is no small service to give the reader, as Dr. Heath has here done, a lively sense of the scientific atmosphere in which Euclid wrote and of his indebtedness and through him that of all subsequent time to his predecessors and contemporaries. Aristotle's statement, quoted by Heath from the "*Posterior Analytics*," that, "other things being equal, that proof is the better which proceeds from the fewer postulates or hypotheses or propositions," reminds one of the famous dictum enounced sixteen hundred years later by the "Doctor invincibilis," William Occam: *Entia non sunt multiplicanda præter necessitatem*. Nothing conveys better the animating spirit of the

modern critical movements in logic and mathematics.

The remaining 273 pages of the first volume are devoted to books I. and II. of the "Elements." The entire discourse is conducted in the most admirable manner. First are given in clear, bold, beautiful type the definitions, axioms and postulates of book I. Each of these is then taken up in order, restated in Greek followed by the English equivalent, and made the subject of an elaborate and lucid historical and critical commentary. The extent of Dr. Heath's commentaries may be inferred from the fact that no less than eighty-five large pages are occupied by discussion of the thirty-three definitions, axioms and postulates of the first book, the immense wealth of the material presented being gathered from all the principal sources from pre-Euclidean times to the present. Then follows the statements and demonstrations of the propositions of book I. with critical discussion of each. The remaining twelve books are treated in similar fashion. The third volume closes with the so-called "Book XIV." by Hypsicles, a note on the so-called "Book XV.," a carefully prepared list of addenda et corrigenda, an index of Greek words and forms, and an excellent general index to the entire work.

Dr. Heath has been animated by no narrow or partisan spirit. Like every other well-informed student of mathematics, he is well aware of the fact that the time is long since gone when the reading of Euclid was indispensable to one who would become a learned or a productive geometrician. And in so far as this new edition may be regarded as a plea for the "Elements," it is an enlightened plea, one entirely worthy of its great theme, the noblest plea in English speech for the Alexandrine classic.

The content of Professor Murray's book has been taken chiefly from his "Infinitesimal Calculus," though some matter relating to indeterminate forms, solid geometry and applications to motion has been added, and the treatment of several topics has been revised. Among the noteworthy features of the work may be mentioned that it contains more than can be properly read in the time usually given

in the best schools to a first course in the calculus; that in view of this fact certain articles have been indicated as constituting a course suitable for "students having a minimum of time"; that the book begins with a discussion of certain problems designed to foreshadow the nature of the calculus and a presentation of such algebraic notions as are of most frequent use in the calculus; that the subject is presented with modern regard—rather too much than too little, if it errs in either respect—for precision and rigor; that, though the subject is divided into differential calculus and integral calculus, the notion of anti-differentiation is presented in connection with that of the direct process; that, with a view to facility of applications, the view of integration as summation is put in advance of the other view; that numerous examples including simple applications to geometry, physics and mechanics, with illustrative solutions, are inserted in connection with the development of cardinal ideas and processes, a table of answers being given at the end of the volume; that unusual care has been given to accentuation of important matters; that especial attention has been accorded to the concepts of speed, velocity and acceleration; that, for alternative or fuller treatment of numerous ideas, the reader is referred to a good deal of the better and more accessible literature; and that there is given a brief introduction to differential equations and a table of integrals. The work is adequate to the needs of the college student, to the technological student and to the rarer spirit preparing for higher flights.

Professor Johnson's book is an abridgment of his "Differential Calculus" and is based on the method of rates. It is distinguished by the absence of the histological methods of the rigorists. Things are presented pretty much at their face values, being shown graphically rather than laboriously proved by help of the refined logical machinery brought in from across the sea. The English is excellent, everything moves along with the calmness, dignity and facility of an elder day, and the reader, while acquiring much useful knowledge, will acquire also a degree of confidence that in these critical times is apt to be rare.

and is apt also to suffer mitigation in the course of subsequent study.

C. J. KEYSER

COLUMBIA UNIVERSITY

Hopi Songs. By BENJAMIN IVES GILMAN, Secretary of the Museum of Fine Arts, Boston, Mass. Hemenway Southwestern Expedition. A Journal of American Ethnology and Archæology. Fifth and Concluding Volume. Pp. xi + 235. Boston and New York, Houghton, Mifflin Company. 1908.

The text of the volume is divided into three sections: I., The Rote Song of the Hopi; II., The Phonographic Method; III., Notation, Diagrams and Comments. Seventeen Hopi songs are included in section III. A brief account of The Hemenway Southwest Expedition closes the volume.

The author opens his treatise by saying:

The study of Hopi, or Moqui, singing, to which this volume is devoted, completes an inquiry into Pueblo music begun in 1891 with a study of Zuni melodies. The records upon which both investigations have been based were obtained in Arizona by Dr. J. Walter Fewkes, now of the Bureau of Ethnology, Washington, at the time in charge of the Hemenway Southwestern Expedition, who first applied the phonograph to the preservation and study of aboriginal folk-lore.

Of his previous study the author writes (p. 11):

The major thesis of the "Zuni Melodies"—that Pueblo music is without scale—is strongly confirmed by this cumulative evidence. The diatonic form of the Hopi songs is (a) harmonic necessity or (b) apperceptive illusion. In large measure their adiatonic features are at once (c) intentional and (d) inexplicable by interpolation and transposition. The minor thesis of the "Zuni Melodies"—that "In this archaic stage of the art the scales are not formed but forming"—is rather weakened than corroborated by a closer study of Pueblo music. Its bent toward change inspires a doubt whether, unless by outward compulsion, it would ever submit to the trammels of a system. It appears an unhistoric rather than a prehistoric art.

Under the head Scales an Instrumental Product; the Voice Determining their Gen-

eral Form, the Ear, the Hand and the Eye their Varieties, the author skillfully proceeded to show that "Although the voice provides the raw material for scale building," the instruments have rendered service, so that

It would appear that while still disembodied music tends to remain adiatonic, though always of necessity diatonoid. Only when incarnate by instrumental constraint does it chose, because it must, the best of all possible yokes.

Other factors have influenced scale development so that

Scales may result with which the voice has had little to do, giving back to music, at the convenience and pleasure of ear and hand and eye, a semblance of the liberty of its vocal stage.

Under the head of Freedom, a characteristic of Pueblo music, the author writes:

Apart from the tendency to consonant intervals no metes and bounds to invention manifest themselves in these melodies, and they may apparently be altered by every performer.

In this connection a footnote calls attention to a fact presented at Berlin in 1888 before the International Congress of Americanists that

The anatomists of the Hemenway Southwestern Expedition found the hyoid bone of the ancient skeletons exhumed on the Rio Salado exceptionally elastic in structure. The position of this bone at the base of the tongue makes it an important factor both in speech and song.

This fact should not be forgotten when considering the data presented in this volume as of wide application. Nor can the statement that songs "may apparently be altered by every performer" be accepted as true of Indian songs in general. Accuracy in the rendition of a song, particularly of one that was a part of a religious ceremony, was insisted upon. In some of the tribes a mistake, or variation, in singing a song, constituted so grave a matter that it put a stop to the ceremony, until after a rite of contrition had been performed; that being finished the ceremony had to begin afresh. That there were slight variations in pitch and intonations was true, but they were such as occur among ordinary singers and did not affect the movement and flow of the melody, which the

singers were careful not to disturb, as the song in all religious rites was regarded as a message to the supernatural.

Section II. deals with The Phonographic Method. The author says of the phonograph: It "makes possible a hitherto unheard-of thing, the detailed study of an individual performance of music. It opens a field of investigation, that of the actual events of which music consists, which has hitherto been accessible to observation in only a very limited way—while a performance lasts, and in so far as it can afterward be recalled by memory." From the premise that "Music is an art of interval and measure primarily, and one of timbre secondarily" the author proceeded to a phonographic study of interval in Hopi singing. He says:

With a series of tests not psychological but physical I endeavored both to find the principal limitations of the instrument by the trial of various conditions of inscription and reproduction, and to determine the degree of exactness of its best performance. The method consisted mainly in noting the amount of variation in the rapidity of pulsations of sound called beats produced between a phonographic reproduction of a note held continuously and another note known to be of constant pitch.

Then follows a lengthy account of his work upon these tests and the conclusion:

As an apparatus for the reproduction of textures of interval the phonograph may fairly be called an instrument of precision.

Of the "method and symbolism of the notation" we read:

Like the records of Zuni music these . . . are the result of an attempt to judge the tones delivered by the phonograph by means of the sense for difference of pitch alone, without aid from the sense of interval. My aim has been to make a separate estimate of the pitch of each individual note of each performance, through its comparison with one or more of the series of tones at intervals of a tempered semi-tone, or 100 cents, given in the notes of an ordinary harmonium. This comparison was made, as before, by silencing the phonograph the moment the note to be judged had been reached, and immediately thereafter sounding a harmonium note. . . .

For the expression of "the minute scale of fourteenths of a tone made the basis" of his

records the author adopted modifications of the historical notation by which he says:

There is thus afforded for each of the fourteenths of a tone assumed as the steps in the scale of these notations a gradation of position easily distinguishable from every other.

He further remarks:

The attempt to follow the musical practice of non-European peoples with such minuteness must justify itself, either on the ground that accuracy of observation is a thing worthy to be aimed at for its own sake, or on the ground that in this branch of research such a degree of it has veritable value for purposes of theory.

Section III. is composed of the presentation of each of the seventeen Hopi songs; given first on the usual clef, next the phonographic record according to his plan of notation, then a chart showing the "Course of Tone," followed by more or less elaborate "Comments." In some of these latter the author shows a fine appreciation of "these wild flowers of fancy, the wanton yield of naïve delight in the vocal production of interval," as in connection with "Snake Song No. 4" where he says:

The interest of the song lies in its stately rhythm, occasionally delicately varied; and in this deliberate ascent, as if from level to level of the singers native mesa, with a pause midway in each to rally loiterers.

The volume represents much careful work and is a valuable contribution to the study of the phonetics of some kinds of Indian singing. The quality of tone is not touched upon and unfortunately the songs under consideration do not present a wide range of rhythms so that that interesting aspect is not dwelt upon. All the records under examination are from single singers. The Indian solo singer is apt to waver more in pitch than when he sings with a group. A number of voices not only strengthens the tone but steadies the interval. Moreover, comparatively few Indian songs are intended to be sung by one voice only, so that such records as those presented in the volume can hardly be regarded as representative of Indian music. They do not picture the songs as they appeal to the Indians, nor does the dissection of tones, as here so ably given, assist our race to dis-

cern the beauty that lurks in a vast number of the songs of the American Indian.

ALICE C. FLETCHER.

SPECIAL ARTICLES

THE DORSAL SPINES OF CHAMELEO CRISTATUS, STUCH

SINCE the discovery of the long-spined Pelycosauria, in Texas, no similar condition has been reported in any living form. Cope referred to the dermal spines of *Iguana* and *Basiliscus* as the nearest condition to that of the fossil forms. Baur noted one or two lizards in which one or two spines were a little

been figured and have never been referred to in explanation of the Permian forms.

Unfortunately this gives us no hint of the use of the elongated spines in the ancient forms. Only two species of the genus, *cristatus* and *montium*, have the elevated spines; the others have a crest supported by dermal rods. The habits of the forms are not sufficiently well known to make any suggestion as to the use of the crest or spines. It is perhaps significant that the chameleons are a highly specialized and decadent group just as the Pelycosauria were and that there is a decided tendency to develop seemingly

Vertebral column of *Chameleo cristatus* Stuch, from Efulen Kribi, Cameroon, showing elevated neural spines.

longer than the others. Through the kindness of Dr. A. G. Ruthven, curator of the Museum in the University of Michigan, I have been enabled to examine a specimen of *Chameleo cristatus* from Efulen Kribi in the Cameroon district, sent to the museum of the university by the Rev. Geo. Schwab, a missionary. The accompanying figure shows the condition of the spines of the vertebrae. The elevated neural spines beginning with the axis extended to the tenth caudal and then rapidly diminish in size on the long and slender tail. At the base of the larger spines there is a very slight enlargement indicating the attachment of the dorsal muscles which reached to that point. The upper ends of the spines were attached by a strong thread of connective tissue and the interspaces between the spines were filled by a very thin membrane of the same tissue. A few scattering threads of muscle were dispersed over the membrane. The condition of this specimen is of great interest as it shows almost exactly the conditions which have been imagined to exist in the Pelycosauria. In the literature of this group I find the presence of the elevated neural spines mentioned but they have not

useless horns and spines in other parts of the body just as there was in the Pelycosauria. It leaves one with the same impression of some sort of physiological excess of growth.

UNIVERSITY OF MICHIGAN

ON THE CHEMISTRY AND DEVELOPMENT OF THE YOLK PLATELETS IN THE EGG OF THE FROG (RANA PIPIENS)

THE yolk platelets in the frog's egg contain 6 per cent. of lecithin and 94 per cent. of a proteid having the following composition: 1.21 per cent. of phosphorus, 1.32 per cent. of sulphur and 15.14 per cent. of nitrogen. I used gravimetric methods in determining phosphorus and sulphur and the Kjeldahl method in determining nitrogen. This composition and the precipitation reactions of the proteid indicate it to be a nuclealbumin related to the vitellins and ichthulins of the yolk of the eggs of birds and fish, hence I will call it batrachiolin.

In the germinal vesicles of the ovarian eggs nucleoli arise from the chromatin. These nucleoli grow and multiply by fission and budding, and during the fall of the year migrate

into the cytoplasm, where they break up into finely granular masses called yolk nuclei. The yolk nuclei become more or less diffused through the cytoplasm, and, especially toward the egg membrane, give rise to the yolk platelets, which are at first minute, but grow during the winter to large size. Thus the nuclealbumin of the yolk platelets is derived from the nucleoproteids of the nucleus.¹ Whereas I am entirely ignorant of the steps by which a nucleoproteid might be changed into a nuclealbumin, the phosphorus content of the egg nuclealbumins (.4-1.5 per cent.) is about the same as that of the native nucleoproteids studied by Halliburton.² We might compare the migrating nucleoli to the trophochromatin of the protozoa and metazoa.³ Whereas the nucleolus is more acidophilous to stains than the idiochromatin (chromosomes), it is more basiphilous than the general cytoplasm, and I see no objection to calling it trophochromatin. Goldschmidt⁴ found the chromidia (trophochromatin) of some protozoa to give rise to "glanzkörper" or glycogen granules which might be compared in function to the yolk platelets of the frog's egg.

Whereas I found that the nucleoli were of greater specific gravity than the nuclear sap, and could be thrown out of the germinal vesicle by centrifugal force, there is no indication that gravity aids in the normal extrusion of the nucleoli. Such migration of nucleoli is a wide-spread phenomenon in animals and plants.⁵

THE STRUCTURE OF LILY PISTILS

IN an extended study of the structure of the pistils of Liliaceæ some results have been reached that warrant the publication of this

¹The amphibian nucleolus is said by Carnoy and Lebrun to contain a small amount of nuclealbumin.

²*Jour. of Physiol.*, Vols. 17 and 18.

³Cf. Moroff, *Arch. f. Zellforschung*, Vol. 2.

⁴*Arch. f. Protistenkunde*, Vol. 5.

⁵Walker and Tozier, *Quart. Jour. of Exper. Physiol.*, Vol. 2.

preliminary note pending the completion of the work.

The pistils of the lilies are in general alike. However, certain differences exist among them (1) in regard to the formation of the partition walls of the ovary and (2) in regard to the development of the ovules. It is the prevailing opinion among botanists that the margins of the carpels in the Liliaceæ infold to form the partition walls of the ovary and also to produce the ovules. This is true of some lilies but it is not true of all lilies. It has been found that certain lilies develop the partition walls of their ovaries, also their ovules, from the middle portion of their carpels. In this type of ovule-production the midribs of the carpels become thicker, push in to the central axis of the ovary, unite and produce the ovules.

The following plants have been found to develop their ovules from the midribs of their carpels: *Lilium longiflorum* Thunb., *Lilium longiflorum eximium* Nichol., *Lilium candidum* Linn., *Erythronium albidum* Nutt., *Convallaria majalis* Linn., *Tradescantia bracteata* Small, *Zebrina pendulata* Schnitzl., *Tulipa* sp.

THE UNIVERSITY OF NEBRASKA

SOCIETIES AND ACADEMIES

THE IOWA ACADEMY OF SCIENCE

THE twenty-third annual meeting of the Iowa Academy of Science was held at the State University, Iowa City, on April 31 and May 1. A public meeting was held on the evening of April 30 for the presentation of the address of the president, Professor Samuel Calvin, on "The Work of the Iowa Geological Survey," and a lecture by Professor William A. Locy, of Northwestern University, on "The Service of Zoology to Intellectual Progress." Before the beginning of the evening program Professor C. E. Seashore gave demonstrations of the tonescope in his laboratory.

In the progress of the two sessions of the academy the following papers were presented:

Comet C, 1908 (Morsehouse): D. W. MORSEHOUSE.

An account of the comet discovered in September, 1908, while photographing at the Yerkes Observatory.

The Polyporaceæ of Fayette, Iowa: GUY WEST WILSON.

Some Parasitic Polyporaceae: C. D. LEARN.

The present paper embodies the results of a field study of the commoner local species of the family. The economic and pathological aspect of *Polyporus ignarius*, *P. fulvus*, *P. everhartii* and *Elfvigia megaloma* are discussed.

An Anatomical Study of the Roots and Rhizomes of a Few Weeds: L. H. PAMMEL and ESTELLE D. FOGEL.

It is a very common practise in agricultural literature to refer to the rhizomes of quack grass and germander and other ground stems of this kind as roots. The morphology indicates that these are stems beyond a doubt. On the other hand the underground portions of the milkweed, Canada thistle and horse nettle are also referred to as roots by the farmer and correctly so, and yet quite a number of botanists have fallen into the error of calling these structures stems. The common morning glory is a stem. The histological structure shows beyond a doubt that they are true roots.

The More Important Factors concerned in the Production of Plant Diseases: L. H. PAMMEL and CHARLOTTE M. KING.

A brief survey and review of the fungus diseases occurring upon cultivated plants for twenty-five years in the state of Iowa. Giving dates for the epidemics of rusts and causes leading up to it, also a discussion of the more general problems of plant diseases and their relation to climatic conditions.

Plant Distribution in Iowa in Relation to Geologic Formations: B. SHIMEK.*The Sand-dune Flora of Iowa*: B. SHIMEK.*The Flora of Iowa Rock, a Small Rocky Island in Puget Sound*: ROBERT B. WYLIE.*Notes on Spore Formation in Ulva*: ROBERT B. WYLIE.*Slime Moulds of the Yosemite*: THOMAS H. McBRIDE.

Preliminary report: (1) the locality: (a) altitudes, (b) general climatic conditions; (2) the season of collecting, and conditions influenced by altitude; (3) list of species taken, with notes; (4) probable results of further explorations.

Okoboji Laboratory: THOMAS H. McBRIDE.*Some Features of Iowa Ground Waters, II.*: W. S. HENDERIXSON.*The Training of the Technical Chemist*: J. S. STAUBT.

This paper and the one following were presented

before the Iowa Section of the American Chemical Society and were read before the academy by invitation.

The Influence of Copious Ingestion of Water: STELLA A. HARTZELL.*A Hysteresis Curve*: D. W. MOREHOUSE and HARRY WOODROW.*The Googler Primary Cell*: HARRY WOODROW.*On the Use of the Balance*: LEROY D. WELD.*The Fifth and Seventh Cranial Nerves of Plethodon glutinosus*: H. W. NORRIS.

A criticism of a recent paper by Dodds. The supposed anomalies in the fifth nerve of *P. glutinosus* are found to fall into line with the common arrangement in urodele amphibians.

The Migration of Nervous Elements into the Dorsal and Ventral Nerve-roots of Pig-embryos: ALBERT KUNTZ.

Embryological evidence is presented to show the fact of migration of nervous elements from the neural tube of the embryo into the dorsal and the ventral nerve-roots. An attempt is made to determine the nature of such migrating cells. General inferences touching neurological problems.

The Unios of the Muscatine County Loess: B. SHIMEK.

The following papers were read by title:

The Asteroid, 1906, W. E.: ELLIS B. STAUFFER.*Further Studies of the Eastern Nebraska Flora*: CHARLES E. BESSEY.

Studies are now being made in the department of botany of the University of Nebraska of the plants now and formerly used by the Indians of eastern Nebraska, especially the Omaha tribe. It is found that many species of plants were formerly used that are not now in use, and within the last few years some plants have been brought into use that had not been previously used. It is hoped that a preliminary report can be made by the middle of the year.

The Estimation of Arsenic and Cobalt in Smaltite: NICHOLAS KNIGHT.

The complicated reactions, oxidation of the arsenic with chlorine. The separation of cobalt. The change in the valence of cobalt from two to three.

An Analysis of the Fruit of Viburnum nudum: NICHOLAS KNIGHT.

A continuation of the chemical study of wild fruits from Sylvan Beach, New York. The extraction and determination of the sugars. The organic acids. The extractions of the oils with ether.

The simplification equivalent of the oils. The weight of the ash and the determination of the ash constituents. The per cent. of the various constituents of the fruits.

The Action of Manure on a Certain Iowa Soil: E. B. WATSON.

The Solubility of Portland Cement Proved: G. G. and A. J. WHEAT.

The advanced studies on cement are demonstrating the power of water, at normal temperatures to dissolve and carry through a double filtering crucible. The silicates of lime and the aluminate of lime, as silicates and aluminates and these same dissolved silicates refuse to yield their calcium to HCl, but do yield after the soda carbonate fusion.

Some Geological Effects of Artificial Drainage in the Wisconsin Drift Region: G. G. and A. J. WHEAT.

Significance of Thrust-planes in the Great Basin Ranges: CHARLES R. KEYES.

The recent discovery of thrust-planes in certain of the desert ranges of the Great Basin region and of late Tertiary strata severely flexed and infolded with early Tertiary lava flows is taken as indicating that the entire region has been subjected to great compression during late geologic times and not to pulling strains that would produce profound normal faulting. The recent-fault theory for the origin of these mountains is therefore very seriously questioned.

Orotaxial Correlation of 'Geologic Terranes and Diastrophism: CHARLES R. KEYES.

The similarity of the two methods is pointed out and their great value emphasized as means of exact correlation of geologic formations. Attention is also called to the fact that the proposition of this method was presented before this academy more than a dozen years ago and a full decade prior to the general acceptance of the principles by geologists generally. It supplants the methods by means of fossils.

Carbonia Column of the Rio Grande Region: CHARLES R. KEYES.

The results of some recent observations are briefly discussed, as bearing upon the Carbonic history of our Iowa rocks. The Carbonic section of the region is very much more complete than in the Mississippi Valley; and in fact more extensive than anywhere else on the North American continent.

Hydroids as Ornamental Plants: C. C. NUTTING.
Arterio-sclerosis: W. E. SANDERS.

Birds of Polk County, Iowa: LESTER P. FAGEN.

Some Observations on the Embryology of Chironomus: W. N. CRAVEN.

L. S. ROSS,
Secretary

DES MOINES, IA.

THE TORREY BOTANICAL CLUB

THE meeting of April 28, 1909, was held at the New York Botanical Garden, with Dr. Tracy E. Hazen in the chair.

Dr. William A. Murrill, chairman of the cryptogamic section of the committee on the local flora, made a report in which the following suggestions were submitted:

(1) The publication of keys and lists of local species for field use; (2) the preparation of a map of the territory included; (3) cooperation with other botanical clubs within or bordering on this territory; (4) cooperation with the field committee in the selection of suitable places for excursions and the care of cryptogamic material collected on these excursions; (5) the use of a given space in *Torreya* for notes upon and additions to the local flora; (6) a joint meeting at an early date with the phanerogamic section of the committee on local flora.

The scientific program consisted of a discussion of "The Cactuses of the West Indies" by Dr. N. L. Britton.

The speaker referred to the distribution of cacti in the West Indian Islands and the regions inhabited by them; these are mostly on the southern side of the larger islands, where the rainfall is very low and where these plants are very abundant, certain portions of the southern side of eastern Cuba and of Jamaica being actual cactus deserts. On the smaller islands the cacti grow less abundantly and mainly at low altitudes. The genus *Rhipsalis* forms an exception to the general xerophytic distribution, its species growing on trees and cliffs in relatively moist regions. Southern Florida contains several species similar to some of those growing on the Bahamas and in Cuba or identical with them. After a preliminary description of the plants the meeting adjourned to the propagating houses of the New York Botanical Garden, where specimens of living cacti, including nearly all the known species of the West Indies, were exhibited and described.

THE BIOLOGICAL LABORATORY OF THE BUREAU OF FISHERIES AT WOODS HOLE, MASS.

REPORT OF THE PAST YEAR'S WORK, AND ANNOUNCEMENT FOR THE COMING SEASON

In the spring of 1908 two of the larger rooms of the laboratory were equipped for chemical investigations, and during the succeeding summer these rooms were occupied by five chemists who were engaged upon various problems of organic analysis. The purchase of books for the library has been continued, and five new periodicals have been added to the list of those which will henceforth be received here. These are the *American Journal of Physiology*, *American Journal of Anatomy*, *Journal of Experimental Zoology*, *Anatomischer Anzeiger* and *Centralblatt für Physiologie*. A considerable number of volumes, including the back numbers of several important journals, were loaned for the season by the library of the Bureau at Washington, and it is hoped that this profitable arrangement will be continued in the future. The entire library of the Woods Hole laboratory has been transferred to glass cases, and will henceforth be more effectively protected against the summer fogs.

Thirty-one investigators were occupied with various researches in marine biology or biochemistry during the past season. Of these eighteen received salaries from the bureau, either as investigators or as scientific assistants. In addition nine other assistants were comprised in the laboratory staff. The subjects of research were as diversified as in past seasons, though problems of economic importance perhaps received a rather larger share of attention.

RECEIVED intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-street, New York, N. Y.

Among the topics of investigation may be mentioned: chemical analyses of the tissues and the eggs of certain marine organisms, the natural history of the sea-mussel and other mollusks, the reactions of marine organisms to light and to chemical stimuli, hybridization in fishes, the parasites of fishes, taxonomic studies of coelenterates, bryozoa and crustacea, and various other problems in general physiology, ecology, cytology and embryology.

The season was marked by an endeavor to bring about more intimate social relations among the investigators of the Fisheries Laboratory themselves, and between the latter and those of their neighbor, the Marine Biological Laboratory. With this object in view, several informal "smokers" were held in the course of the summer, and by general agreement these occasions were regarded as highly successful, both in the furtherance of friendly cooperation among the local scientific colony and the stimulus given to individual efficiency. At the close of September, Woods Hole was visited by a considerable delegation from the Fourth International Fisheries Congress, which had just concluded its formal session at Washington. The visitors were conveyed to Woods Hole from Wickford, R. I., upon the steamer *Fish Hawk*, leaving for Boston by rail on the same day. The delegation included some distinguished fisheries experts and men of science from Europe, Asia and North and South America.

At the present writing, the long-heralded report upon the local biological survey is very nearly completed and with little doubt will be ready for publication by the close of the present summer. The following sections of this laborious work are now finished: (1) The list of organisms (so far as identified) which were taken at each of the 424 dredging stations. This station record covers over 750 manuscript pages and in-

cludes about 450 species of animals and about 90 species of plants. (2) Maps showing the distribution of all of those species which were taken at ten or more of the dredging stations.¹ There are more than 200 of these representing the fauna, about 40 representing the flora. Other charts have been prepared, showing character of bottom, water temperature and density at various seasons, geographical relations, etc. (3) The census of the local marine fauna and flora, based upon the survey dredgings and upon all other available data. The resulting annotated list occupies about 700 manuscript pages and records the occurrence of some 1,400 species of animals and over 250 species of plants. (4) The general account of the project, with summarized results, discussion, etc. This has only been finished in the rough. A final draught will be made during the next few months, thus completing the report. A brief discussion of the work, containing some of the more important general conclusions, was prepared by the writer for the Fourth International Fisheries Congress, and is being published in the proceedings of that congress.

In response to an appeal from the health board of Salem, Mass., the director of the laboratory was instructed by the commissioner to detail one of the investigation staff to visit that city for the purpose of inquiring into the cause of a serious mortality among the fishes in that neighborhood. Dr. C. L. Alsberg was chosen for this mission, and proceeded at once to the seat of the trouble. He found that enormous numbers of fishes, chiefly herring and whiting, had been stranded along the waterfront of the city, causing serious discom-

¹ This basis of selection has not been adhered to strictly either for animals or for plants. In the case of the plants the number of such species would in reality considerably exceed that given.

fort to the inhabitants, if not actually menacing their health. There was no evidence of an epidemic among the fishes, as had at first been feared. Great schools of them had come into dangerously shoal water, perhaps as the result of pursuit by predaceous species, and had been stranded by the receding tide. There was thus nothing to be done but to remove the offal, and to pray that the catastrophe might not be repeated.

A few notes seem worth while regarding certain species of animals which have been taken at Woods Hole, during the past year. *Orthopristis chrysopterus*, a fish belonging to the family *Hæmulidæ*, which is common farther south along our Atlantic coast, was taken for the first time in the vicinity of Woods Hole. A specimen of the "flasher" or "triple-tail" (*Lobotes surinamensis*) was captured at Nantucket. There have been very few previous records of the occurrence of this fish locally. A small crab, *Dissodactylus mellita*, which lives in association with echinoids of the "sand dollar" type, was taken in Vineyard Sound, though probably not for the first time. A curious case deserves mention of one fish becoming encysted within the body of another. In May, 1908, Mr. V. N. Edwards chanced to open a large hake (*Urophycia tenuis*) in the course of his search for parasitic worms. The hake seemed to be in perfect health and its stomach was nearly filled by a whiting, which had been recently swallowed. Upon examining the body cavity, a long slender object was found, completely inclosed within a fold of the peritoneum. This proved to be a dead fish, having a decidedly "mummified" appearance. Its body was 25 cm. in length. Skin, and for the most part fin-rays, were lacking, and the flesh was much shrunken and extremely hard. From the general bodily proportions of this fish, and the presence of a frontal spine, it is believed

by the writer to belong to the genus *Leptophtidium*. Several members of this genus have been taken off the coast, at great depths, and it seems likely that the present specimen came from a considerable distance. It had probably been swallowed by the hake, escaping subsequently through the wall of the stomach, perhaps by using the frontal spine as a perforating organ. The stomach of the hake had evidently healed completely after this adventure.

The fact does not seem to have been hitherto recorded that the "hawk-bill" or tortoise-shell turtle (*Eretmochelys imbricata*) not infrequently reaches the coast of southern New England. Its occurrence has not been mentioned in any list of the reptiles of Massachusetts, and I have found no reference to its having been observed north of North Carolina. Small specimens of both the loggerhead and hawk-bill are, however, occasionally taken in local fish traps, and one or two of the latter have been preserved in the museum of the laboratory. A specimen ten or twelve inches long was taken among floating *Sargassum* by Mr. Edwards in August, 1908, and was kept for some time in the shark pool of the station. I learn from Mr. Edwards that individuals as large as eighteen inches long are not infrequently captured. This species is readily distinguished from the loggerhead (*Caretta caretta*) by the presence of four costal shields, instead of five as in the latter, and from the green turtle (*Chelonia mydas*) by the presence of two prefrontal plates on each side of the head.

The following is a list of the investigators present during the season, together with their subjects of research:

Carl L. Alsberg, Ph.D., instructor in biochemistry, Harvard University: (1) chemical composition and food value of certain marine organ-

*Now pharmacologist in the Bureau of Plant Industry.

lama; (2) investigation of death of fishes at Salem, Mass. (*Salaried investigator.*)

Charles B. Bennett, graduate student in Brown University, assisted Dr. Alsberg in chemical investigations above mentioned. (*Scientific assistant.*)

William M. Clark, A.M., assistant in chemistry, Williams College, likewise assisted Dr. Alsberg. (*Scientific assistant.*)

Edgar D. Congdon, A.M., Austin teaching fellow in zoology, Harvard University: a comparison of the marine and the brackish-water representatives of certain species of mollusks. Mr. Congdon also acted as librarian of the laboratory.

Bradley M. Davis, Ph.D., Cambridge, Mass.: (1) botanical section of the biological survey; (2) cytological studies of marine algae. (*Salaried investigator.*)

Donald W. Davis, professor of biology, Sweet Briar College: the effect of conditions acting at the time of the fertilization of the fish egg upon the subsequent size and proportions of the organism. (*Scientific assistant.*)

Irving A. Field, professor of chemistry and biology, Western Maryland College: (1) the utilization of the dogfish and mussel as food; (2) the life history of the sea mussel. (*Salaried investigator.*)

A. J. Goldfarb, graduate student in Columbia University: the influence of the nervous system upon the regeneration of various organisms.

Charles W. Hargitt, Ph.D., professor of zoology, Syracuse University: the morphology and taxonomy of local coelenterates. (*Salaried investigator.*)

George T. Hargitt, A.M., Austin teaching fellow, Harvard University: the embryology of hydro-medusae.

George W. Heimrod, Ph.D., assistant in Rockefeller Institute of Medical Research: (1) studies of the enzymes found in marine organisms; (2) preparation of the flesh of fishes for future analysis.

Edwin Linton, Ph.D., professor of biology, Washington and Jefferson College: the helminth parasites of fishes. (*Salaried investigator.*)

Samuel O. Mast, Ph.D., Johnston research scholar, Johns Hopkins University: the reactions of certain marine organisms to light. (*Scientific assistant.*)

James W. Mavor, graduate student, Harvard

*Now instructor in the Woman's College of Baltimore.

University: the development of the coral, *Agaricia fragilis*.

Jesse F. McClendon, Ph.D., instructor in zoology, University of Missouri: the chemistry of the echinoderm egg. (*Scientific assistant.*)

William J. Moenkhaus, Ph.D., professor of physiology, University of Indiana: the development of certain fish eggs, after fertilization with spermatozoa from other species or genera. (*Salaried investigator.*)

R. O. Mullenix, Ph.D., professor of biology, Yankton College: the development of the neurofibrillae in the eighth cranial nerve of *Fundulus heteroclitus*.

Raymond C. Osburn, Ph.D., instructor in zoology, Barnard College, Columbia University: a systematic study of the bryozoa of the Atlantic Coast. (*Salaried investigator.*)

George H. Parker, Ph.D., professor of zoology, Harvard University: (1) the sensory reactions of the dogfish; (2) tests of the hearing of various fishes. (*Salaried investigator.*)

Fernandus Payne, graduate student, Columbia University: studies of chromosomes.

Henry F. Perkins, Ph.D., assistant professor of zoology, University of Vermont, spent a few days in quest of early stages of *Gonionemus*.

Alice Robertson, Ph.D., instructor in zoology, Walleale College: identification and classification of bryozoa collected by the steamer *Albatross*, in the northwest Pacific in 1906.

A. P. Romine, instructor in biology, State Normal School, Bellingham, Wash.: a study of local crabs.

George G. Scott, A.M., instructor in the College of the City of New York: changes in the specific gravity of the blood of fishes, resulting from changes in the density of the water. (*Scientific assistant.*)

R. W. Sharpe, M.Sc., instructor in biology, DeWitt Clinton High School, New York City: systematic studies of marine entomostraca.

Ralph E. Sheldon, Ph.D., assistant in anatomy, Chicago University: the reactions of fishes to chemical stimuli. (*Scientific assistant.*)

Bertram G. Smith, instructor in zoology, Syracuse University: the embryology of *Cryptobranchius*.

Francis B. Sumner, Ph.D., director of the laboratory: (1) report upon the biological survey; (2) studies of the ecology of the native periwinkle, *Littorina palliata* (with Jas. W. Underwood).

James W. Underwood, teacher of biology, high school, Negaunee, Mich.: color variation and other features of the natural history of *Litorina paludata*. (*Scientific assistant*.)

Donald D. Van Slyke, Ph.D., assistant in Rockefeller Institute for Medical Research: the action of enzymes.

Edward M. Weyer, Ph.D., professor of philosophy, Washington and Jefferson College: the behavior of the remora.

The facilities of the laboratory have likewise been utilized to a considerable extent during the months not comprised in the regular summer session. Dr. B. M. Davis and Mr. George T. Hargitt occupied tables during the spring of 1908, and Dr. Davis has enjoyed the privileges of the laboratory throughout the entire winter of 1908-9. For the past three years the director has resided almost continuously at Woods Hole, occupied primarily with the report upon the biological survey. In the compilation of this report he has been assisted, first by Mr. J. W. Underwood and later by Miss E. M. Chapman. From time to time requests have been received from investigators at various institutions for materials for embryological or other studies, or specimens of marine plants and animals. Some of these persons have come to Woods Hole for this purpose. While it is far from the policy of the bureau to operate a supply department for the free distribution of marine specimens, such requests for materials have in special cases been granted. In general it may be said that the demand for a marine laboratory which shall be operated continuously throughout the entire year is increasing, and it is the frequently expressed hope of many persons that the Bureau of Fisheries will in time be able to make provision for the maintenance of such a station at Woods Hole.

During a portion of the coming season the director will be relieved of all administrative duties in connection with the lab-

oratory, in order that he may complete several pieces of unfinished work. During this period, Dr. Raymond C. Osburn, of Columbia University, will serve as acting director.

It is requested that applications for laboratory tables shall be submitted at the earliest possible date.

FRANCIS B. SUMNER

WOODS HOLE, MASS.,

April 30, 1909

THE PLANS AND WORK OF THE GEORGE WASHINGTON UNIVERSITY

THE discussions in the public press seem to call for an authoritative statement of the educational work and condition of the University.

1. Prior to 1902, when the present administration assumed charge, there was a day college, with less than a hundred students, and a faculty of eleven professors and teachers. There was also the Corcoran Scientific School, doing undergraduate work in the evening, which was conducted by the professors of the day college. These professors received salaries in the day college ranging from one thousand to eighteen hundred dollars a year, and seventy-five per cent. of the students' fees for the evening work. This arrangement was made between the faculty and the university to prevent any liability on the part of the university for the expenses of the evening college. In this college there was some work given in engineering and architecture. The Law School was conducted by lawyers in practise and judges in service, no one giving his entire time and attention to its management or to teaching. The Medical School was conducted in the same way, by practising physicians, there being no professional teachers employed giving their whole time to the educational work.

2. The first change adopted under the present administration was to discontinue the Corcoran Scientific School, merge it with Columbian College, and require all class-room

work to be done between the hours of nine in the morning and half-past six in the afternoon; the laboratories and libraries to be kept open, with assistants, until ten o'clock. The objects in view were to unite the student body and create a spirit of unity, and place all the college work upon the basis of absolute equality. The entrance requirements were advanced to conform with those of eastern colleges. Part of the work taken by full-day students and all of the work of the part-day students was given in the afternoon between half past four and half past six o'clock, so that the two groups came into class-room association. As the students employed during the day do not have the same time for the preparation of their class work, they were limited to a less number of hours per week. This increased the period within which the half-day students could earn a degree by one or two years. The effect of this change upon the faculty was to put all of the professors on a salary basis, cutting out the fee system. In the faculty there were differences of opinion as to the wisdom of this change.

8. The next change inaugurated was to employ professional teachers in the professional schools. In the Law School, four men, exclusive of the President, are now employed, who give their entire time to teaching. They teach by the case method, which requires much time in preparing for class work and trained ability to impart knowledge. This does not displace or in any way discount the excellent work done by lawyers and judges of very high standing who are still conducting work in the school. Its purpose was to establish in the City of Washington a law school of the type prevailing in the best universities, where men who desire the most thorough training in the law would be able to secure it. A full day law course beginning in the morning was established, with fourteen hours work per week required. This was done to attract the students who give all their time to study and desire to have it fully occupied. An afternoon course of ten hours per week is given for students employed through the day. Thus the needs of the two groups of students were met.

To the students giving part of their time a less number of hours is required, but the same quality of teaching provided. By increasing their attendance to four years afternoon students may cover the entire work while full day students complete it in three years. The part-day students may receive the Bachelor of Law (B.L.) degree at the end of the third year. This plan has met with hearty approval from students who are serious-minded and desire to secure the best legal education. These changes have raised our standing in the Association of American Law Schools, and enable our graduates to pass successfully the Bar examinations in all the states. Not one graduate last year failed in these examinations.

4. The changes in the Medical School involve practically the same educational problem and were met with the same objections as those in the Law School. The administration advocated the extension of the laboratories and the employment of specially trained men to teach the laboratory courses. This was done and resulted in the employment of four professional teachers on regular salaries to do this work. The expense involved was the increase of the salary list and the expenses in establishing and maintaining the laboratories. Another change was to increase the clinical teaching, first by requiring men in their graduating year to give their full time to the work in order that they might give full time to the clinic. This was afterwards still further advanced by making the school a full day school, so that students would have their whole time both for laboratory and clinical courses. Didactic lectures are still continued and should be, but the laboratory and clinical teaching is essential to a scientific training. The effect of these changes was to decrease the number of students and the income, at the same time increasing the expenses; but it enables us to retain our position in the Association of American Medical Schools, and enables our graduates to take the medical examinations before all State Boards. It gives us a better standing among medical institutions, and

most of all, will, when the plan is thoroughly worked out, give to each student a thorough training that will enable him to take a high position in his profession, and thus give additional reputation for the school.

5. It will be observed that in all these changes there was but one object in view, to improve the educational standards and methods, bringing them as near as our resources would permit for the standards and methods prevailing in the best institutions. We would not claim to have attained all we hope to attain. This is not the fault of the plans but because of the lack of funds to completely carry out the plans in all particulars. The advances made, however, are great and the advantages to the students and the university are manifest. It would be a matter of profound regret to have these new developments abandoned. Washington needs professional schools of the highest type and should have them.

The next change made was to segregate the work done in engineering and architecture from the liberal arts college. The College of Engineering, the division of architecture, were established. This involved some increase in the expenses, but it has added a fine body of over 200 students to the university, thus increasing the income from students' fees. Additional work was provided in purely technical courses, and through the generous gifts of apparatus by friends, a good laboratory in electrical engineering was created, and a beginning made in a mechanical laboratory. In establishing the College of Engineering it was not intended to make a complete polytechnic school, but simply to put in technical courses and allow the students to take about half of their work in the liberal arts college.

The moving cause for this change was to give the young men of Washington an opportunity within their means to prepare themselves for skilled service in the great professions of engineering and architecture. Washington, with few industrial or commercial openings, offers few opportunities for high grade skilled employment to the rising genera-

tion. Without university training in these lines, young men stand little chance of succeeding in the states, where the great state universities and privately endowed institutions are training thousands of young men in these lines. That the situation demanded the establishment of these schools is demonstrated by the large body of students from this city who are taking the courses.

7. In the act of congress providing for the organization and a salary scheme for the teachers in the public schools of the District of Columbia it was provided that new appointees to certain positions in the high schools should have a college education, including the subjects of psychology and pedagogy. These requirements shut the doors of these positions to young people in the district who are financially unable to go to colleges outside of the district. This prompted us to put in the division of education. In this division, we have a professor of psychology, a professor of education, and two lecturers upon school administration. It is not claimed that this is a rounded teachers' college, but it does give, by very competent teachers, the courses required by the act of congress, which, taken in connection with the course for the bachelor of arts degree in the College of Liberal Arts enables the graduate and holder of a teacher's diploma to secure the highest positions in the public school system. These technical courses are substantially taken care of by the tuition fees of the students taking the courses. These fees do not cover the whole expense of the education of the student, for the great body of the work is taken in the College of Liberal Arts. We assumed that if the tuitions would meet the expense of the technical work, we should add to the numbers taking the liberal arts course, meet a pressing demand and serve our city in advanced education of teachers for the public schools.

8. The College of the Political Sciences is the outgrowth of the old school of jurisprudence and diplomacy. Every scholar in this field recognizes that there are peculiar advantages for carrying on this work in the city of Washington and that the effect upon students

living for a time in this city and observing the powers of the federal government in action is most beneficial to the country at large. This college has received special contributions towards its current expenses. During the present year it received ten thousand dollars pledged for next year. We have limited the scope of the work to two years of undergraduate and two of graduate study, making the entrance requirement two years of college work. This brings all students, for the first two years, into the Liberal Arts College, but allows them free election of the courses in the political sciences in the third and fourth years of their undergraduate studies. The object in making it a separate organization was to secure contributions and endowment for the work which could not be done successfully if it was merged in a college of the liberal arts. Experience in other institutions has shown that a faculty of the political sciences is more successful when conducting the work within its own field.

9. It will be observed that all of these small branches that have put out from the main college are confined entirely to technical courses and are intended to furnish the minimum amount of such courses required to meet existing demands in the District of Columbia. The center of it all is the College of Liberal Arts, and in each of these special branches the new students have increased the numbers in the Liberal Arts College, while their tuition fees have nearly paid the salaries of the technical teachers, except in the College of the Political Sciences, and there the deficiency has been made up by special contributions.

10. In order to carry out these plans and do the work on the lines proposed, it has been necessary to fit up and maintain new laboratories and to increase the library facilities. In 1902 we had five or six thousand volumes of books in the whole institution; to-day we have about forty thousand volumes.

11. The foregoing constitutes all of the policies of the present administration which have been criticized or condemned by members of the college faculty and I put them forth without argument, in order that the

people of Washington may determine whether these plans have been educationally sound, and whether or not a university serving the community in all of its needs is worthy of their confidence and support. Professors who opposed these educational advances, finding that there was call for efforts to maintain the university, went to the trustees and proposed to take the university and run it for the fees, provided the president was removed and their policies could prevail.

Had this concerted effort been successful with the trustees, not only would the "salary of the president" have been saved, but this new work would have been stricken down and many of the new professors would have been discharged. It is a matter of conjecture whether, had this plan succeeded and fifteen or twenty professors been discharged, there would have been a proportionate increase in the agitation of the public mind.

13. In regard to the pensioning of teachers, so far as I understand it, it has always been construed where a pension system existed that when a professor has become entitled to a pension, either by length of service or by age limit, he has the right to retire voluntarily at any time, and the university has the equal right to retire him when for any cause it seems expedient to do so. In the recent action it became necessary to reduce the expenses about twenty-five thousand dollars, and to distribute that retrenchment among each of the departments of the university. Of necessity the services of some of the teachers had to be dispensed with, and in selecting the ones to be retained, all things being equal, it was natural to retain those who were thoroughly in harmony with the general plans and development of the university.

The action of the Carnegie Foundation in assuming that the university had no option but could retire only those eligible who voluntarily sought retirement seems to be contrary to the usual construction of pension systems. Waiving this point, however, their action in our case was hasty and arbitrary. As the secretary sought to give the widest possible publicity to the injury done the university by

giving their letter to the press, I give my letter in reply, which states the facts regarding the procedure. It reads as follows:

June 11, 1909.

DR. HENRY S. PRITCHETT, *President*,

The Carnegie Foundation for the Advancement of Teaching.

Dear Sir: Your letter of June fourth was received while we were in the midst of Commencement week, and for that reason the answer has been delayed. Immediately upon the receipt of your communication it was presented to a special meeting of the Board of Trustees.

It is a matter of sincere regret on the part of every one who has read the letter that your organization, with its high aims for the advancement of all true efforts in educational work, should have taken this action without any notice to the university and without giving it any opportunity to be heard upon the real and apparent reason for your action, as shown by your letter. That an institution of learning, with fifteen hundred students, should be struck such a blow without warning or opportunity to correct any defects in its administration that might be shown, is difficult to comprehend, and as expressed by others than myself, almost impossible to believe. Your agent arrived here on Wednesday morning, the second instant, and was shown every courtesy that could be accorded to him. Our deans, who have the immediate charge of the educational work, although in the midst of examinations, gave up their time and showed him every consideration. At the end of the examination he came to my office and expressed in the most hearty and gentlemanly way his appreciation of the attention that had been shown him by the secretary of the university and by the deans. I asked him to make any criticisms that he desired to make to me, and assured him that we should be glad to correct any defects in our system that could be corrected. He made a few remarks regarding some of the work, part of them complimentary and part in friendly criticism, but there was no intimation that it was contemplated, or that the investigation was with a view to terminating the relation between the foundation and this university. Since the action has been taken it has been stated by Dr. Sterrett that the agent spent two hours with him and part of the time with Dr. Gore regarding the matter of their retirement. What they said of course I do not know. Had there been a fair investigation of that question with a view to your

taking action regarding it, I respectfully submit that the other side of the question should have been heard. To assume that there is but one side to an issue is not only unfair but tends to create the impression that it is desired to hear only one side.

* * * * *

Since coming here in 1902 I have had but one aim, and that is to gradually make the institution a true university, serving this community in all possible lines of higher education—a community that has pressing needs for such advantages.

From my acquaintance with you I can but believe that upon mature reflection you will see the injustice that has been done, and will accord a hearing to the university.

With very great respect, I am,

Sincerely yours,

CHARLES W. NEEDHAM

15. In reference to the financial conditions of the university, the treasurer has handed me a comparative statement of the assets of the university in 1900 and the assets at the close of the fiscal year 1908, which shows that in 1900 the gross assets of the university, including everything, were \$905,279.45 and the liabilities were \$325,719.61, leaving the net assets \$579,559.84. In 1908 the total assets were \$1,365,508.22, the liabilities \$489,004.24, leaving the net assets \$876,498.98. The increase in the indebtedness during the last period was occasioned by the completion of the new Medical School building and the Hospital in 1901-2, and indebtedness created to meet deficiencies in current expenses.

Of the foregoing assets the productive investments in 1900 were \$223,509.65. In 1908 they were \$127,740.91. This change in the productive assets was caused by the drain upon the funds occasioned by the increase in the cost of maintaining the university. The contributions toward the current expenses were insufficient to meet the annual deficit, and thus funds, which were properly applicable, had to be used to pay the salaries and current expenses or close the doors to progress.

It must be borne in mind that the university has always had a deficit. Its productive funds have never been sufficient to meet its expenses. In round figures \$125,000 of the

indebtedness in 1900 represented borrowed money to pay accumulated deficits. Since the new policy went into effect the annual deficits have necessarily been larger than they were before, and have been incurred with the authority of the board of trustees, in the belief that the improvement of the educational standards and work, with the increased numbers of students coming in upon higher entrance requirements would so demonstrate the needs of such a university in this district that broad-minded and beneficent men would come to its aid and support the movement. It had been demonstrated by numerous efforts that no money could be obtained for the old university.

We need to secure for the expenses next year, 1909-10, \$55,000 to keep the university going on its present plans. This budget has been approved by the board, and if the money is not provided it will again have to be paid out of existing assets. It is apparent that this process of meeting annual deficits out of the assets can not go on very long. The university must have financial support. If congress will give to the District of Columbia the same consideration that it gives to every state and territory and Hawaii and Porto Rico, by extending the benefits of the Morrill act to this district, and designating this university to receive the money, the appropriation would pay a little over one half of the deficit next year. We are doing the work required under the Morrill act in the mechanic arts to justly entitle us to the benefits of this fund. There is no other institution in the district that is carrying on work of university grade in the mechanic arts. If the citizens of the District of Columbia will do as Baltimore did for Johns Hopkins when it was in financial straits and what has been done in other cities for other institutions, raise by subscription a fund of \$200,000, payable in five annual installments of \$40,000 each, this, with the benefits of the Morrill act, would enable the university to go forward on its present plans and do its work for the district. With five years free from financial anxiety we could hope to thoroughly establish the university upon its new

basis, by appeals to the country at large for adequate endowment.

CHARLES W. NEEDHAM,
President

THE GEORGE WASHINGTON UNIVERSITY,
WASHINGTON, D. C., June 21, 1909

PRESENTATION OF A BUST OF DARWIN

At the Darwin celebration held in Cambridge, England, from June 22 to 24, a bronze replica of the bust of Darwin, by Mr. William Couper, which was presented by the New York Academy of Sciences to the American Museum of Natural History in February last, was presented to Christ's College by the American delegates on behalf of those who recognize the influence of Darwin on American thought and science. A letter recently received from Professor Shipley states that the acceptance of this bust would take place at the time of the garden party on June 23.

The American institutions and individuals that have voluntarily contributed towards defraying the expense of this gift, its transportation and its erection in Cambridge (about \$1,000) are as follows:

Ann Arbor—Research Club of University of Michigan.

Cambridge—Dr. Alexander Agassiz, Dr. Theobald Smith.

Chicago—University of Chicago.

Cold Spring Harbor, L. I.—Dr. Charles B. Davenport.

Ithaca—Cornell University.

New Haven—Connecticut Academy of Arts and Sciences, Professor Tracey Peck, Professor Russell H. Chittenden.

New York—Columbia University, Dr. E. B. Wilson, Professor Henry Fairfield Osborn, Mr. Charles F. Cox, Mr. M. Taylor Pyne, The American Museum of Natural History, Dr. Harmon C. Bumpus, Brooklyn Institute of Arts and Sciences.

Pasadena—Dr. George E. Hale.

Philadelphia—University of Pennsylvania, Philadelphia Academy of Natural Sciences.

Pittsburgh—Carnegie Institute.

Princeton—Princeton University, Professor W. B. Scott, Professor O. W. Richardson.

Washington—Smithsonian Institution, Dr. Robert S. Woodward, Washington Academy of Sciences.

SCIENTIFIC NOTES AND NEWS

Dr. WILLIAM H. WELCH, professor of pathology in the Johns Hopkins University, has been elected president of the American Medical Association.

PROFESSOR E. W. MORLEY has been elected honorary president and Dr. W. H. Nichols acting president of the Seventh International Congress of Applied Chemistry, which has accepted the invitation extended by the congress through the president and the secretary of state, to meet in this country in 1912.

Mr. ORVILLE WRIGHT and Mr. Wilbur Wright were presented on June 19 with the gold medal authorized by congress, a medal on behalf of the state of Ohio and a medal on behalf of the city of Dayton.

GOVERNOR SLOAN, of Arizona, has appointed, as territorial geologist, William P. Blake, Sc.D., emeritus professor of geology in the University of Arizona.

PROFESSOR F. W. PUTNAM has been appointed professor emeritus of anthropology in the University of California.

THE University of Pennsylvania has conferred its doctorate of laws on Dr. Charles B. Penrose, formerly professor of gynecology at the university.

BROWN UNIVERSITY has conferred its doctorate of science on Dr. C. V. Chapin, professor in the Harvard Medical School and superintendent of public health in Providence; on Mr. J. B. F. Herreshoff, the chemist of New York City, and on Dr. W. C. Gorgas, of the Isthmian Canal Commission. Dr. Gorgas has also received the doctorate of laws from Jefferson Medical College.

Dr. GEORGE E. MACLEAN, president of the Iowa State University, gave the commencement address at Syracuse University and the degree of doctor of laws was conferred on him.

THE University of Glasgow has conferred its doctorate of laws on Dr. C. S. Sherrington, professor of physiology at Liverpool and on Mr. W. H. Maw, editor of *Engineering*.

THE senate of the University of Michigan has presented Dr. Angell with an address en-

grossed in parchment and bound in silver covers with symbolic designs.

A COMMITTEE has been formed in Dublin to present Professor Fraser with some token of respect on the completion of his twenty-five years as professor of anatomy in the school of the Royal College of Surgeons in Ireland.

Dr. ANDREW WALKER McALESTER, professor of surgery and dean of the School of Medicine of the University of Missouri, has resigned from the faculty of the school with which he has been connected since 1873.

PROFESSOR JOHN CLELLAND, of the University of Glasgow, who has held the chair of anatomy since 1877, and Professor William Jack, who has held the chair of mathematics in the same institution since 1879, are about to retire from active service.

Dr. W. P. MASON, professor of chemistry in the Rensselaer Polytechnic Institute, has been elected president of the American Waterworks Association for the meeting to be held next year in New Orleans.

THE Harben gold medal for eminent services to the public health, has been awarded to Professor E. von Behring, of Marburg, and Lieutenant-Colonel W. B. Leishman, professor of pathology, Royal Army Medical College, has been appointed the Harben lecturer for the year 1910, and Professor Angelo Celli, of Rome, the Harben lecturer for the year 1911. The Harben lectures for 1909 were delivered by Professor R. Pfeiffer, of Breslau, on June 21, 23 and 25.

LIEUTENANT EDWARD H. SHACKLETON arrived in England on June 10. He will address a meeting of the Royal Geographical Society at the Albert Hall on June 28, when the special gold medal of the society will be presented to him by the Prince of Wales. At a luncheon given in his honor at the Royal Geographical Society on June 15, Lieutenant Shackleton announced that he contemplated another Antarctic expedition at an early date.

A CABLEGRAM to the daily papers states that Professor T. C. Chamberlin, Dr. E. D.

Chamberlin and Mr. R. T. Burton have returned to Pekin, after investigations on behalf of the University of Chicago, of China's material and intellectual resources and the possibility of American cooperation in developing education in China.

DURING the present season the Oklahoma Geological Survey will carry on two lines of investigation. Professor D. W. Ohern will have charge of a party in the oil fields in the northeastern part of the state, investigating the occurrence of clay, cement rock, building stone and other structural material in that region. Mr. L. L. Hutchinson, assistant director of the survey, will have charge of investigations on asphalt in southern Oklahoma.

PRESIDENT WHITNEY has appointed the following committee to represent the American Chemical Society in connection with the Hudson-Fulton celebration: M. T. Bogert, *Chairman*, New York; L. H. Baekeland, Yonkers; W. G. Tucker, Albany; M. A. Hunter, Troy; Edward Ellery, Schenectady.

MR. WILFRED H. OSGOOD, of the U. S. Biological Survey, has accepted a position as assistant curator of mammalogy and ornithology in the Field Museum of Natural History of Chicago and will take up his new duties on July 1.

DR. S. A. BARRETT has been appointed to the curatorship of anthropology of the historical department of the Public Museum of the city of Milwaukee. An addition to the building, covering about 19,000 square feet and four stories in height, exclusive of basement which will contain a large lecture hall and assembly rooms, is now being erected.

MR. WILLIS L. MOORE, chief of the Weather Bureau, is at present in England.

DR. H. D. REED, assistant professor of neurology and vertebrate zoology in Cornell University, will leave this country on July 22 for study in Europe. He will be absent about a year and a half. Six months of this time will be spent at the Naples Marine Laboratory and a year at Freiburg.

MR. L. C. SNIDER, A.M., University of Indiana, who was recently elected to a position of

chemist of the Oklahoma Geological Survey, will spend the summer at the United States Geological Survey testing laboratories at Pittsburg, Pa., conducting a series of tests on Oklahoma clays.

MRS. ELLEN H. RICHARDS, of the Massachusetts Institute of Technology, who is to preside at Denver at the sessions of American Home Economic Association, is to deliver an address before the Western Association of Technical Chemists and Metallurgists on "The two modern dragons—bad air and dust." From there she will go to the University of California to deliver two courses of lectures on eugenics and sanitation.

A PORTRAIT of the late George Chapman Caldwell, professor of chemistry at Cornell University, has been painted, for presentation to the university by his colleagues and former students. Dr. Andrew D. White made the presentation address and Dean Crane received the portrait on behalf of the university.

A MONUMENT in honor of the eminent surgeon Mikulicz, who died in 1905, has been unveiled in Breslau with an address by his successor Professor Küttner.

At a meeting of subscribers to the statue of Lord Kelvin for Belfast, held on June 2, it was resolved unanimously that the statue be erected in the grounds of the city hall instead of in the grounds of Queen's University.

THE twenty-sixth annual convention of the American Institute of Electrical Engineers will be held at Frontenac, Thousand Islands, N. Y., from June 28 to July 1, under the presidency of Mr. Louis Ferguson, of Chicago.

THE people of Honolulu already have pledged half of the money asked for by the Massachusetts Institute of Technology for the maintenance of an observatory which the institute proposes to establish at the Brink of Kilauea for the study of volcanic action. Professor T. A. Jaggar will spend the summer there.

THE department of geology at the University of Michigan has received from Professor Dean C. Worcester, Secretary of the Interior

for the Philippine Islands and at one time a member of the faculty of the university at Ann Arbor, the gift of a unique collection of photographs of the volcanoes in the Philippine Islands. These excellent photographs, more than two hundred in number, have been taken mainly by Professor Worcester himself in connection with his many journeys through the islands, and for the most part are of volcanoes which have never before been photographed. Among them are a considerable number of prints of a volcano 1,600 feet in height, which in 1871 was suddenly thrown up over a fissure in a level plain only 400 yards distant from the town of Catarman on the Island of Camiguin, north of Mindanao.

MR. ZACCHEUS DANIEL, of the Princeton Observatory, discovered a comet June 15^h.80 Greenwich mean time, in R. A. $1^{\text{h}} 39^{\text{m}} 54^{\text{s}}$, Dec. $+28^{\circ} 55'$. The comet is visible in a small telescope. "Motion rapidly northerly."

DR. EDWIN B. FROST, director of the Yerkes Observatory and managing editor of the *Astrophysical Journal*, announces that the subscription price of the journal has been increased from four to five dollars. He writes: "It is obvious that a periodical of a strictly scientific character like the *Astrophysical Journal*, even though conducted without expense for contributions or for editorial or clerical assistance, can not be self-supporting. The large number of costly illustrations, which are necessary to properly elucidate the text and to place before the reader as nearly as possible the author's original scientific evidence, constitute a large item of expense, which has been increased very materially of late by concerted action of engravers. The considerable amount of tabular matter accompanying many of the articles also adds largely to the cost. In spite of the use of monotype composition for much of the text, the cost of manufacture has been gradually increasing, in accordance with the general tendency toward higher prices. The point has been reached where a reduction in the size of the journal and in the average number of illustrations must be made, or the subscription price be increased. The annual deficit of the

journal has been met by a subsidy from the University of Chicago, which in the last two years has been \$2,000. An increase in this subsidy can not be requested. With the advance in subscription price it is expected that the size of the journal and the number of illustrations will be maintained as during recent years. A careful comparison, in respect to amount of text and illustrations, has been made with all the principal contemporaries of the *Astrophysical Journal*, both foreign and domestic. This shows that even after the present advance, the journal will be relatively cheaper than other periodicals of its class."

AN investigation as to the practicability of reforesting the great areas of forest lands which have been devastated by fire and which are now lying barren and unproductive is now being carried on by the United States Forest Service in the Olympic National Forest in Washington. The area selected for the experiments comprises several thousand acres on the Soleduck River, and was at one time covered with a magnificent forest of Douglas fir. It was first burned over in 1890 and again in 1895. A third fire over almost the same area occurred in 1906, destroying the last remnant of the original forest, leaving the entire area treeless. In some regions a second growth of trees will come in naturally after a burn, in the course of a few years time, and where this happens artificial means of securing reproduction is not necessary. There are, however, other burns, where new growth does not come in readily, due to the adverse climatic conditions, absence of seed trees, or perhaps to the impoverishment of the soil by repeated fires. These areas are often of very large extent and in such cases some means, such as planting trees or sowing seed, is necessary to restore the forest. The burn in the Olympic Forest is of this nature and the Forest Service is planning to conduct a series of experiments to determine the proper methods of reforesting the area. Douglas fir will be the species used. It is believed that on the greater part of the area simply scattering the seed over the ground in the fall before the

snow falls or in the early spring will be sufficient to start a new growth. On other portions of the area, however, where a growth of grass and weeds has covered the ground, it will probably be necessary to work the seed into the soil by raking or dragging brush over the ground. In some localities sowing by what is called the seed spot method in which several seeds are dropped together in spots and covered with soil will probably be successful. To test these various methods five experimental plots have been selected. These represent the various conditions found on the burn, such as difference in slope, altitude, exposure and vegetation. This fall a large quantity of Douglas fir seed will be collected and a quantity sown on each plot. Next spring the experiments will be repeated and it is expected that the results obtained will indicate what methods and what seasons of the year are best adapted to the conditions found on this burn. When this is accomplished the Forest Service will be in a position to commence the reforestation of the Soleduck burn on a large scale and to reseed large areas each year. It is believed also that the results obtained will be of value not only in solving the problem of restocking the burn in the Olympic National Forest, but that much will be learned concerning the best methods of reforesting denuded areas in other forests throughout the Pacific northwest, where conditions are similar, and that thus the work may be largely extended.

UNIVERSITY AND EDUCATIONAL NEWS

THE University of Wisconsin, the University of Michigan, the University of Minnesota and the University of Toronto have been admitted to the regular pension system of the Carnegie Foundation for the Advancement of Teaching.

MR. JOHN D. ARCHBOLD has given \$300,000 to Syracuse University, to pay the mortgage on the ground of the university which was placed in order to build the gymnasium.

SWANTEMORE COLLEGE will receive \$125,000 from the General Educational Board, providing the sum of \$875,000 is raised within

two years by the college. The sum of \$187,500 has already been subscribed.

DR. C. T. WILLIAMS, of Pembroke College, has given £2,500 to Oxford University for scholarships in physiology and human anatomy.

THE School of Mining affiliated with Queen's University in Kingston, Ont., is about to erect a new chemical building which will cost nearly one hundred thousand dollars and will probably be ready for occupation in October, 1910. In the meantime, indeed very soon, two or three appointments to the teaching staff will be made. A building for mining and metallurgy will also be put up at a probable cost of fifty thousand dollars. It is the gift of a member of the staff of the school, Professor Nicol, of the department of mineralogy. The chemical building is provided by the Ontario government.

THE department of zoology and geology at the Massachusetts Agricultural College will this year conduct a ten days' camp at the seashore for introductory work in marine zoology. The camp will be established at Groton, Connecticut, at the mouth of the Poquonnock River. Work will begin at the close of the college year. The department thus aims to supplement its courses in general and economic zoology. The work will consist mainly in the study of habits, habitats and ecological problems, in collecting for study, dissection and preservation and in photographic work. The privileges of the excursion are open to students of elective undergraduate courses. Reports will be required and credit will be given for the work as a part of the undergraduate courses. The work will be in charge of Professor C. E. Gordon.

THE Rev. Henry H. Appel, of York, has been elected president of Franklin and Marshall College, at Lancaster, Pa. Mr. Appel is a son of the late Thomas G. Appel, who was president of the college for many years.

DR. HAROLD PENDER, of New York City, has been appointed professor of electrical engineering in the Massachusetts Institute of Technology.

OSCAR A. JOHANNSSEN, assistant professor of civil engineering at Cornell University and author of researches on the biology of water supply, has accepted the professorship of entomology in the University of Maine.

DR. J. E. KIRKWOOD, formerly an investigator with the Continental-Mexican Rubber Company in Mexico, has been appointed assistant professor of forestry and botany in the University of Montana.

CHAS. H. TAYLOR, a graduate student in geology at the University of Chicago, has been appointed assistant professor of geology in the University of Oklahoma.

PROFESSOR H. A. WILSON, F.R.S., of King's College, London, has accepted the appointment of professor of physics in McGill University.

DR. ARTHUR LAPWORTH has been appointed a senior lecturer in chemistry at the University of Manchester. He is the son of Dr. Lapworth, F.R.S., professor of geology at Birmingham, and is at present head of the chemical department of the Goldsmiths' Institute, New-cross.

DISCUSSION AND CORRESPONDENCE

MYLOSTOMID DENTAL PLATES

IN a recent contribution by Dr. L. Hussakof on "Relationships of American Arthroires" (*Bull. Amer. Mus. Nat. Hist.*, 28, art. 20), a peculiar dental element is made known under the caption of *Dinognathus ferox*. The designation applies to a supposed new genus and species of Arthroires, of doubtful family relations, and whose characters are imperfectly definable. The position of the plate in the mouth is held to be indeterminate, although remark is made that "its form is not suggestive of having been set in a titanichthid mandible."

Knowledge of this unique structure is the more welcome, since, as the present writer believes, it dispels the mystery of the missing upper dentition of *Mylostoma terrelli* Newb. That the peculiar plate in question belongs to the same sort of creature, if not indeed to the identical species as that established by New-

berry upon the evidence of a solitary mandibular plate (now the property of the Museum of Comparative Zoology), seems practically certain. At all events it can be provisionally associated with the type of *M. terrelli* with the same confidence that actuated Newberry's theoretical correlation of upper and lower dental plates of *M. variabile*—an hypothesis afterwards confirmed beyond peradventure by Bashford Dean.

The mylostomid nature of the novel dental plate under discussion is unmistakable, one might even say self-evident, the moment it is perceived to be a compound instead of simple element, representing in its entirety the forwardly placed pair of palato-ptyergoid dental plates common to Arthroires and Otenodipterines. Among the latter, *Heliodus lesleyi* furnishes an analogous instance of fusion of the corresponding parts.

The newly discovered dental plate is significant for yet another reason, namely, for enlightening us as to the extent to which the components of the upper dentition of Arthroires are capable of fusion *inter se*. Certainly in *Dinomylostoma*, and presumably, also, in *Mylostoma* proper, there is a single pair of vomerine, and two distinct pairs of palato-ptyergoid dental plates. In Dinichthyids, so far as known, the two last-named pairs on either side are fused into a single "maxillary" element or "shear-tooth." *Dinognathus* is peculiar in having the forward pair of palato-ptyergoid tritors fused into a single plate, whose periphery accords fairly well with the antero-external contour of the mandible—that is, on the assumption that Newberry's so-called *M. terrelli* and the newly described *Dinognathus ferox* relate merely to different parts of the same dental apparatus. It is pertinent to observe further that a rounded eminence occurs in the median line anteriorly, as shown in Dr. Hussakof's figure, corresponding in size and position to surface elevations of the homologous plates in *M. variabile*. The manner in which these eminences interact with depressions in the functional surface of the lower dentition has been discussed elsewhere. As to the occurrence of vomerine teeth and a

posterior pair of palato-pterygoid dental plates in the new genus described by Dr. Huasakof we are still without information, but the presence of the latter, at least, may be predicated as a logical necessity.

Newberry's recognition of *M. terrelli* as a distinct species is justified by appreciable differences between the mandible upon which it was founded and those characterized by him as *M. variabile*. Generic differences between it and other Mylostomids are now indicated by the characters of its (supposed) upper dental pavement. Hence, in order to give effectiveness to the theoretical association of parts here proposed, it becomes necessary first of all to unite the two "species" of *ferox* and *terrelli*; and secondly, to substitute the latter specific title, on grounds of priority, as genotype of *Dinognathus*. C. R. EASTMAN

HARVARD UNIVERSITY

A LAWYER ON THE NOMENCLATURE QUESTION

DISCUSSIONS of the past year or two in scientific journals—more particularly in SCIENCE—move the undersigned to free his mind on the above subject. Trained first as a zoologist and later as a lawyer, he now follows law as his vocation and zoology as his avocation. This is a good combination of schoolings for the appreciation of some aspects of the nomenclature question.

In the first place, nomenclature as an art—and it is already an art and a very specialized one at that—is not science at all, but law pure and simple. It is the art of interpreting and applying to various states of natural fact the unnatural man-made rules which have grown up during the last century and a half, partly by unwritten custom, partly by precedents, and partly by conscious legislation, just exactly as other systems of law have grown up. Doubtless it is because the scientific men who handle this body of law have no legal training and try to handle it as if it were science (as some undoubtedly suppose it to be) that they make such a prodigious bungle of it. Their chief blunder is that they endeavor to carry on and administer and build up this system of law *without any courts!* Consequently

every piece of litigation (conducted most uneconomically and unsystematically by loose correspondence and articles in scientific journals which ought to be reserved for better things) is indeterminate and each litigant remains of the same opinion still and acts accordingly. If merchants and business men were so stupid as to try to administer the complicated rules of their game for themselves, to the ruinous neglect of their real interests, without special training in the making and interpreting of rules, and *without tribunals for the settlement of their questions*, we should have an exact parallel to the situation which has arisen in zoology and botany.

Some may doubt my dictum that the field of nomenclature is a field of law, not science. Let me add to this dictum one to the effect that many, if not most, of the questions of nomenclature (like many questions of law) are of utterly insignificant importance so only that they be settled *one way or the other, quickly, definitely and permanently*. Then let me cite an instance—and a fair one too—illustrative of both dicta.

Picking up the April number of the *Proceedings of the Malacological Society of London*, I see that A. J. Jukes-Brown, a competent authority in the malacological world, differs widely and strenuously, though courteously, from our own Dr. Dall (a highly competent authority) as to the nomenclature of certain groups of the Veneridæ. In part his difference turns on different findings and interpretations of facts. These are scientific differences. The scientific methods of which each is master will enable the two men to agree—or if they can not reach the same conclusion then to agree to differ. Neither can, or should, after his final reexamination of the evidence, yield his honest opinion a jot to anybody or to any tribunal. But in part his difference turns on the following point. Dr. Paul Fischer, in his "*Manuel de Conchyliologie*" (etc.), did much rearranging and collating of generic and subgeneric groups. For each group he had the habit of naming one species with the prefix "*ex.*" standing, of course, for "example." Dr. Dall, perhaps not

unnaturally considering it as of little significance whether the species selected as illustrative of a group was called "the type" or "the example" of it, regarded Fischer in these cases as having designated the type with the usual train of consequences under the rules. Jukes-Brown holds that of course Fischer did nothing of the kind, examples not necessarily being types.

I should be willing to argue either side of this if paid for it—but not otherwise! It is a law-point pure and simple and a dry one at that. It is not of the very smallest import to any aspect of science which way it is decided. To flip a coin would be a good way to settle it. Yet in the present state of things it is quite supposable that Dr. Dall and Mr. Jukes-Brown, in order to reach a working agreement as to the nomenclature of the Veneridae which is of scientific import, may feel compelled to give considerable amounts of their time, and considerable space in a crowded journal, to a necessarily inconclusive attempt to thresh it out.

It is a sin and a shame, a reproach to science and scientific men, that the time of master specialists, every available moment of which is needed by science, should be taken up by utterly vain questions like this, which any whipper-snapper just out of a law school could actually handle better than they can because trained for it and not taking it so much in earnest. And their time is taken up by questions like this, and it has to be under the present lack of system.

And what, pray, is the great difficulty in settling these things as they should be settled? If the next International Zoological Congress voted to establish an international court of five members sitting for three months annually to decide in writing every question submitted, with or without argument, taking counsel with specialists when necessary, publishing its decisions in an annual volume with or without the course of reasoning in each case, how many years would it take before the main questions were all settled and the business of the court reduced to a thin trickle of new puzzles? Of course such a court should have absolute power to settle absolutely everything

nomenclatorial except questions of natural fact and scientific interpretation. Equally of course it would have to treat the priority rule as a *prima facie* rule made by sane men for sane men, not as the superstition and incubus it has become. If they saw fit to rule in one auction catalogue as a nomenclatorial source for merely practical reasons, and rule out another for similar reasons, they should have a free hand to do so without feeling that any one by being the first to name, or perhaps mis-name, a natural object thereby acquired a vested right to retard the progress of science for centuries. Of course in the present absence of such a tribunal, or of any tribunal, an absolute priority rule has an excuse as being the nearest present approach to a universal touchstone for our names, and so long as that situation endures systematists are bound to live strictly up to it. But with such a tribunal suggested the direful necessity for it would pass away, and the "Museum Smithianum," 1832, having once been ruled in we could then apply its names and learn them without the probability of someone's discovering next year that the "Museum Jonesianum"—date hitherto unknown—was in fact published in 1831. Nay more, a discovery that the "Museum Smithianum" was a rank forgery and in large part non-binomial need not worry us. Once ruled in or out, mistakenly or not, it stays so. The name "*Octopus*" once adjudicated to be the name of the group typified by *O. vulgaris* L. stays so no matter how clear the proof that the court ought by every known rule to have made it "*Polypus*." Is there any ethical question involved? No. And does it matter to science which it is called? Not an iota so long as we know which.

Would it not tend to "crystallize" and "fossilize" science? No, but it would tend to crystallize and fossilize the artificial Latin nomenclature of science which ought to be crystallized and fossilized, and the sooner the better. Of course no tribunal can ever pass on the question whether a given form is a variety, a subspecies or a species; whether it belongs to this or to that genus or subgenus; what are the limits of a family; nor on any

other question of science properly so called. And equally of course nomenclature can never be definitely settled. But its puerile and yet forbidding aspect can be vastly altered for the better.

Is there any real practical difficulty in the way of doing all I have suggested and doing it at once? Emphatically *no!* Men more trained to cooperation than scientific men—business men, administrators, lawyers, politicians—would have done it long ago.

PERSONAL NAMES AND NOMENCLATURE

THE use of personal names in nomenclature which has been somewhat criticized by various correspondents is perhaps defensible under certain circumstances. While its objections in many instances have been pointed out yet the absurdity of the practise becomes strikingly apparent when one notes such a paper as that on Paleozoic Ostracods in a recent volume of the Proceedings of the National Museum. In all, sixteen generic names are used in the article; nine of these are old and seven new. Among the old names, five are certainly personal in origin, four may not be, although two of these probably are. Among the seven new names, absolutely every one is personal. Either this indicates an extraordinary number of distinguished men in this field or an unfortunate lack of mental energy on the part of the authors.

SIR WILLIAM GAIRDNER'S PAPERS

TO THE EDITOR OF SCIENCE: In response to the wishes of Lady Gairdner and her family, I have undertaken to edit the medical and scientific papers and articles of the late Sir William Tennant Gairdner, and to preface the collection with a biography.

In order to render the work as worthy as possible of the memory of the late professor, I am desirous of enlisting the sympathy and help of his friends. I venture therefore to request through your columns that any one who has in his possession any letters or other

literary remains of Sir William Gairdner will be so kind as to communicate with me.

SCIENTIFIC BOOKS

The Book of Wheat. By PETER TRACY DONDLINGER, Ph.D., formerly Professor of Mathematics in Fairmount College. With 60 illustrations. Pp. xi + 369. New York, Orange Judd Company; London, Kegan Paul, Trench, Trübner & Co., Limited. 1908.

When we think of the great importance of the cereal wheat in the food economy of nations it is surprising that there has not been more written on the subject. The book now before us is something that might well have been looked for years ago. The author has furnished portions of his manuscript at different times to the writer of this review, and the latter has, therefore, known something of what was to be expected in the book itself.

Naturally a writer is likely to give more prominence, in discussing a subject, to those features with which he has come most often in daily contact, and so in this instance there is proportionately not as much space given to the discussion of wheat as a plant as to the milling operations, the commercial and economical position, etc. The work is particularly lacking in its presentation of wheat classification, discussion of varieties and other matters of botanical and agronomic interest. On the other hand, there is a very full discussion of the machinery for harvesting and threshing, crop rotations, fertilizers, marketing, milling, prices, movement and consumption. A commendable feature, also, is the addition of a very complete bibliography, though it must be said that the proof-reading of this bibliography was very faulty.

Considerable attention is also properly given to the topic of diseases and insect enemies.

In making use of the map (page 9) showing wheat distribution, which was formerly published by the U. S. Department of Agricul-

ture, it is unfortunate that the author did not so change it, in accordance with the suggestion of the writer, as to put the durum wheat district in its correct position. This area, however, is properly shown in another map on page 48. Not long after the publication of the first map by the U. S. Department of Agriculture events occurred in the establishment of durum wheat which greatly changed the boundaries of the district.

Because of the lack of special observation and training in particular lines the author is led into making a few peculiar statements, some of which are not well founded; for example, the statement on page 48: "Common bread wheats are usually grown on black soils. These soils are not well adapted to fall wheat, however, for it is apt to winterkill." There is no good reason for this statement, with the possible exception that black soils are often heavy and therefore apt to bake and crack open, thereby exposing the crown and roots to the winter's cold, but even then rolling the ground is a simple remedy. As a matter of fact, winter wheat is very commonly grown on just such soils.

Also, on page 51, it is not clear why the author should say: "Winter wheat may be sown in spring and spring wheat in the fall. Only a very few plants will ripen seed, but when this is continuously sown, *in three years the spring variety will be changed to the winter, and vice versa.*" (Italics are the reviewers.) There are only certain varieties, already on the border of these two groups, that we are yet certain can be thus changed at all, and even these are likely to require much more than three years to become completely adaptable in the other group.

There is a slight inaccuracy in the first paragraph on page 56, which, however, in this case is rather important, as it refers to the introduction of the present hard winter wheat, called here "red winter wheat," from Russia into Kansas. The Department of Agriculture did not, as there mentioned, originally introduce the wheat, but later took active part in extending the area by further importations; it appears that Russian Mennonites first brought the wheat to Kansas.

On pages 121 and 122, after describing the extensive immigration into the Great Plains region and the rapid settlement of that area, saying: "The 'Great American Desert' disappeared from the maps," and "During a series of years in which the rainfall was more adequate than usual, the agricultural areas leaped forward to the west from county to county," the reader is suddenly brought against a fall of cold water by the statement that "Yet the blunt fact remained, and still remains, that many millions of acres were dead, vacant, and profitless simply because of their aridity. This land has little value now, for in many places a whole section does not yield enough to keep a fleet-footed sheep from starving." Without any question much has been said that is extreme on both sides of this question of just how profitable may be the cultivation of these semiarid lands, but doubtless there is a sane, medium ground to be taken. It is certain that, as a rule, much more may be produced than is sufficient "to keep a fleet-footed sheep from starving," but, on the other hand, the proper cultivation of such districts is in no way child's play. No doubt fair average results can be obtained, but the farming must be done by the most intelligent, up-to-date methods.

Under the discussion of milling operations we have, on page 272, the same old diagram of a large flour mill which has been used in various other publications, but which would not be at all an accurate presentation of our present-day, improved mills.

After these statements of some imperfections, of which it must be admitted there do not seem to be many, the author is to be commended for the ample presentation he makes of certain phases of wheat handling, giving a particularly full discussion of the marketing, price and movement of wheat, including dealings on boards of trade, speculation, grain privileges, delivery, etc. There is considerable discussion, also, of storage, grain elevators, the method of bagging on the Pacific Coast, etc.

The book is rather fully illustrated, particularly along commercial lines. It is a book that will be extremely useful not only to busi-

ness men but as a reference work in schools and colleges.

MARK ALFRED CARLETON

U. S. DEPARTMENT OF AGRICULTURE

BOTANICAL NOTES

GENERAL NOTES

ONE of the most interesting of the popular bulletins issued by the United States Department of Agriculture is that on "The Basket Willow" (Farmers' Bulletin 34) prepared by W. F. Hubbard, of the Forest Service. It appears that the growing of basket willows was introduced into the United States about sixty years ago by German immigrants who settled in New York and Pennsylvania. It has now extended south and west and is rapidly spreading over the non-arid regions of the far west. Three species are commonly grown for this purpose, viz., *Salix amygdalina*, *S. purpurea* and *S. pruinosa acutifolia*, and in the bulletin the peculiarities of each are given. How to plant, how to prune and care for the young trees, how to cut and peel the rods, and finally how to prepare them for the market are described in a most interesting manner. Every botanist who is interested in the economic aspects of his science will find this pamphlet worth reading.

Botanists of an ecological turn of mind will find in A. W. Sampson's paper on "The Revegetation of Over-grazed Range Areas" (Circular 158, U. S. Forest Service) an example of how ecology may have some intensely practical applications. In the Wallowa National Forest in northeastern Oregon the sheep owners overgrazed the land, and it became necessary to study the problem of the restoration of the pastures to their original condition. At first this would seem to be an agricultural problem, but its solution called for "an expert in plant ecology (Mr. Sampson) and in the last analysis the problem becomes an ecological one. The paper is commended to ecologists for careful study.

Another agricultural bulletin of high botanical interest is L. H. Smith's on "The Effect of Selection upon Certain Physical Characters of the Corn Plant" (Bull. 132, Ill. Expt. Station) in which are given the results of experiments in breeding corn (maize) with

reference to (1) the height of the stalk, and (2) the declination of the ear from the stalk. By starting with a particular variety of corn and breeding in opposite directions in the fifth generation the average heights of the ears on the stalks are three feet apart. In part this is due to the increased height of the whole plant on one hand, and the decreased height on the other, but it is due still more to the appearance of the ears from higher or lower internodes. Thus the average number of internodes below the high-eared corn was $8\frac{1}{2}$, while the average for the low-eared corn was $6\frac{1}{2}$, and this was reduced to a little more than $4\frac{1}{2}$ in the last generation. Apparently one may breed the ears down to the ground, or up out of reach.

Here may be mentioned W. T. Macoun's "List of Herbaceous Perennials Tested in the Arboretum and Botanic Garden of the Central Experimental Farm at Ottawa, Canada," which contains an astonishingly large number of species (over 2,100), when one thinks of how far north they were grown.

Under the title "The Distribution of Woody Plants in the Pikes Peak Region" Professor E. C. Schneider enumerates 115 species, giving altitudes, distribution and descriptive notes. It is printed in the Colorado College Publication (Vol. XII, Science Series). Fifteen conifers are enumerated, five poplars, fourteen willows, six oaks, etc.

Much more ecological in nature is Professor Ramaley's "Studies in Lake and Streamside Vegetation" (*Univ. Colo. Studies*, Vol. VI.), which deals with the plants of Redrock Lake near Ward, Colo., at an altitude of over 10,000 feet above sea-level. It is, we are told, the first of a series of similar papers. It is beautifully illustrated by many half-tone reproductions of photographs.

That the botanists of Colorado are active is shown by the foregoing, and also by the following titles of recent papers in the *University of Colorado Studies* (Vol. VI.): "Botanical Opportunity in Colorado," by Professor Ramaley; "Studies in Mesa and Foothill Vegetation" (including the "Distribution of Conifers (4 species only) on the Mesas," by

W. W. Robbins and G. S. Dodds, and "Distribution of Deciduous Trees and Shrubs on the Mesas," by W. W. Robbins); and "Bibliography and History of Colorado Botany," by Edith M. Allison. Under the last title several hundred papers are enumerated bearing more or less upon Colorado botany.

Somewhat out of the ordinary is Professor De Loach's bulletin entitled "The Mendelian and De Vriesian Laws Applied to Cotton Breeding" (Bull. 83, Georgia Experiment Station). It is a plea for the application of scientific principles to the breeding of the cotton plant, with illustrations from his own work, and will repay careful reading.

The Report of the State Forester of Wisconsin for 1907 and 1908 contains much interesting, and some encouraging matter for the lover of forests. Especially pleasing is the "half-tone" frontispiece which shows a thrifty growth of young pines which if protected will eventually restock the land with a forest covering.

Not strictly botanical, but worthy of examination, is the Second Biennial Report of the Wyoming State Board of Horticulture, of which the well-known botanist, Professor Aven Nelson, is the secretary. The eastern reader will be astonished at the photographs of fine trees and fruits grown in this new mountain state.

RECENT SYSTEMATIC PAPERS

Another local manual of botany has appeared, this time in a region where such a thing is much needed. Professor J. R. Watson, of the University of New Mexico, has issued as one of the bulletins of the university (No. 49) a pamphlet of a little more than a hundred pages consisting of a "Manual of the More Common Flowering Plants Growing without Cultivation in Bernalillo County, New Mexico." In his preface the author says that it "has grown out of the need of a key to the local plants to place in the hands of his students. None of the manuals published cover this region satisfactorily." Thus finding no systematic manual, he very properly went to work and made one. That is the right spirit for the teacher, and Professor

Watson is to be commended for undertaking the work. And we say this in spite of the poor printing and the numerous typographical errors in the pamphlet. One who has had no experience with the small printing establishments to be found away from the large cities has no conception of the impossibility of faultless typography under such circumstances. So we overlook the *form* of the little manual, and see in it a worthy effort of the author to supply a usable book for his pupils. We should like to see more teachers willing to incur the labor necessary to provide as useful a book as this.

H. Leveille's "Monographie du Genre *Onothera*," begun some years ago, has reached its third part and includes species from No. 38 to 54, i. e., those of the "groups" *Godetia*, *Clarkia* and *Boissduvalia*.

Recent numbers of the "Leaflets of Philippine Botany" issued at irregular intervals by A. D. E. Elmer, of Manila, include articles 23 (November 23, 1908) to 29 (February 15, 1909). The titles are "Synopsis of *Rubus*" (classifying and describing the sixteen species and one variety which occur on the island), "Threescore of New Plants," "The Genus *Itea*" (containing two Philippine species), "A Fascicle of South Negros Figs" (34 species, of which 5 are new), "Gesneraceæ from the Cuernos Mountains," "New Philippine Zingiberaceæ" and "A Score of New Plants." These "leaflets" constitute an interesting little journal of systematic botany.

A NEW LAKESIDE LABORATORY

A very pretty prospectus announces the establishment of the "Lakeside Laboratory" of the State University of Iowa at Okoboji, Iowa, by the alumni of that institution. The location is on a bay on the westerly side of Okoboji Lake, in the extreme northern part of central Iowa, at the highest elevation above the sea of any place in the state. The session covers ten weeks, divided into two terms, the first from June 21 to July 31, and the second from August 2 to August 28. In botany three courses are offered in the first term, namely: (1) mycology, by Professor Macbride; (2)

biology of aquatic plants, by Professor Wylie; (3) the nature of plants, by Professor Wylie. Opportunities are afforded, also, for research work in botany under the direction of the two professors named. In the second term, work is offered in field ecology and plant taxonomy by Professor Shimek. Courses in geology, zoology and nature study also are offered by competent instructors. The management of this summer-school work is in charge of the director of university extension at Iowa City.

CHARLES E. BESSEY

THE UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

SEX AND ITS RELATION TO THE BARRING FACTOR IN POULTRY

W. J. SPILLMAN¹ has suggested that the barring factor and sex in poultry are correlated in such a way that the female is always heterozygous in respect to sex and also barring when present. The male, on the other hand, is always homozygous in respect to sex and may be either homozygous or heterozygous in respect to barring. I have recently performed the following experiments, which bear directly on this point and confirm his theoretical deductions.

Experiment 1.—A Buff Rock male (non-barred) bred to Barred Rock females give, in F_1 , barred males and non-barred (blacks or buff) females.

Experiment 2.—A Barred Rock male bred to Buff Rock females (non-barred) or a Rhode Island Red female (non-barred) gives in F_1 , all barred birds in both sexes.

Experiment 3.—A Buff Rock male bred to F_1 females (non-barred) from experiment 1 gives, in F_2 , chicks which do not show the down pattern characteristic of chicks from barred parents, thus indicating an entire absence of barring in F_2 .

These experiments may be formulated thus: Using B =barring factor, b =its absence; F =the female sex factor, f =its absence or the male sex factor. Assume that B and F can not occur in the same gamete (Spillman). Then,

¹ *Am. Nat.*, Vol. XLII., No. 50, 1908.

Experiment 1 becomes $bf \cdot bf \times Bf \cdot bF = Bf \cdot bf + bf \cdot bF$.

Experiment 2 becomes $Bf \cdot Bf \times bf \cdot bF = Bf \cdot bf + Bf \cdot bF$.

Experiment 3 becomes $bf \cdot bf \times bf \cdot bF = bf \cdot bf + bf \cdot bF$.

Other crosses giving similar results are:

Experiment 4.—A White Rock male (carrying barring as a cryptomere) mated with Brown Leghorn females gives in F_1 both sexes barred.

Experiment 5.—The reciprocal cross, viz., a Brown Leghorn male mated with White Rock females gives black chicks and chicks having a down pattern like that of Barred Rock chicks. These chicks, however, are yet too young to enable a determination of their sex.

Experiment 6.—A White Rock male (carrying barring) bred to Buff Rock females gives, in F_1 , both sexes barred.

Experiment 7.—From the reciprocal cross I have only two birds as yet, both barred males.

Experiment 8.—One of the F_1 barred males from experiment 7 mated with a Buff Rock female gives, in F_2 , barred and non-barred chicks, which are still too young to permit of their sex being determined.

While my results appear to confirm Spillman's suggestion, I wish to point out that experiment 3, rather than experiment 2, 4, 6 or 8, furnishes us the true test of his suggestion, for the reason that the presence of the F factor may simply prevent the B factor from becoming visible under certain conditions. In some experiments, at any rate, I find that the presence of the F factor operates to modify barring, making it appear obscure and blurred as compared with males from the same parents. On the other hand, we may refer this obscuring of barring to some other cause, perhaps the heterozygous nature of the female.

The details of these experiments are reserved for a later paper.

H. D. GOODALE

Since the above note went to SCIENCE some F_2 chicks in experiment 3, have reached the

stage at which barred chicks usually exhibit distinct barring in their first feathers. Such barring is absent in these *F₁* chicks.

**THE TENTH ANNUAL MEETING OF THE
SOCIETY OF AMERICAN BACTERIOLOGISTS
HELD AT BALTIMORE, MD.,
DECEMBER 29-31, 1908**

THE tenth annual meeting of the Society of American Bacteriologists was held in the rooms of the laboratories of pathology and of physiology of the Johns Hopkins University and Hospital, Baltimore, Md., on December 29, 30 and 31, 1908.

Professor H. L. Russell, of the University of Wisconsin, president of the society, occupied the chair.

The scientific program consisted of thirty-two papers, all of which aroused much interest; certain of them are reproduced in abstract below. The society also met in joint session with Section K of the American Association for the Advancement of Science on December 30, when a paper on "Anaphylaxis" was read by one of its members, Dr. M. J. Rosenau, of Washington, D. C.

About fifty-two persons were in daily attendance at the several sessions of the society.

During the sessions the following matters of business were transacted: Dr. William H. Welch, of Baltimore, was reelected to represent the society on the council of the American Association for the Advancement of Science. To fill the vacancy on the Committee on Methods and Identification of Species, caused by the absence of Professor F. D. Chester, Professor C. E. A. Winslow, of Boston, was duly elected. Professor Erwin F. Smith, of Washington, D. C., was delegated to represent the society at the approaching meetings of the International Botanical Congress at Brussels in 1910. The question of the society withdrawing its affiliation with the American Association for the Advancement of Science and transferring the same to the American Society of Naturalists and agreeing to meet with the latter body in the future was warmly discussed. It was decided to sever the present relations and join meetings with the naturalists should they decide to meet apart from the American Association for the Advancement of Science.

The following are the names of the officers of the society elected for the year 1909:

President—Dr. J. J. Kinyoun, Washington, D. C.

Vice-president—Dr. Veranus A. Moore, Ithaca, N. Y.

Secretary and Treasurer—Dr. N. MacL. Harris, Chicago, Ill.

Council—Dr. W. W. Ford, Baltimore, Md.; Dr. F. C. Harrison, Macdonald College, Quebec; Dr. H. W. Hill, Minneapolis, Minn.; Mr. Lore A. Rogers, Washington, D. C.

By the election of the following gentlemen, the limit to active membership in the society, as defined by the constitution, has now been reached, namely, 125:

Dr. Burdett L. Arms, assistant director of the bacteriological laboratory of the Board of Health, Boston, Mass.

Dr. John W. Connaway, professor of comparative medicine, and veterinarian in the College of Agriculture, the University of Missouri, Columbia, Mo.

Mr. George E. Gage, assistant in bacteriology, Yale University, New Haven, Conn.

Mr. Daniel D. Jackson, director of the laboratories, Department of Water Supply, Gas and Electricity, New York City.

Dr. Harry T. Marshall, professor of pathology and bacteriology, University of Virginia, Charlottesville, Va.

Dr. Otto Rahn, assistant professor of bacteriology and hygiene, Michigan Agricultural College, East Lansing, Mich.

Mr. James C. Temple, soil bacteriologist, Georgia Agricultural Experiment Station, Experiment, Ga.

ABSTRACTS OF CERTAIN PAPERS

Acid Fermentations of Milk: E. G. HASTINGS and B. W. HAMMER, University of Wisconsin, Madison, Wis.

In milk, butter and cheese are constantly found organisms identical in all important points with those supposed to be characteristic of certain fermented milks, especially the Bulgarian yoghurt. Production of 3-4 per cent. of acid in milk, growth at high temperature characterize the organism. The therapeutic value which has been ascribed by Metchnikoff and others to the fermented milks, such as yoghurt, is probably due to the composition of the milk, rather than to the presence of the peculiar organism. Since opportunity is constantly offered for the alimentary tract to become seeded with the organism, if it finds favorable conditions for growth in the alimentary tract, it should establish itself, no matter how slight the seeding may be, and we should find it in the feces constantly. Massive seedings can only temporarily establish the organism unless the environment is favorable.

Some Factors concerned in the Fixation of Nitrogen by Azotobacter: CONRAD HOFFMANN and B. W. HAMMER, Bacteriological Laboratories, University of Wisconsin, Madison, Wis.

The possibility of employing azotobacter for artificial soil inoculation, as well as the importance of its existence in soil as a nitrogen increaser, are factors which can not be ignored. With these as a basis, the work reported in the paper of the above title was performed. It appears that some fermentable carbohydrate is essential for nitrogen fixation; the same is true with reference to the presence of phosphorus and some base. The influence of (1) varying amounts and kinds of carbohydrates; (2) of varying kinds of phosphates (mono-, di and tri-forms), and (3) of the period of incubation, were all factors which were considered. The employment of the sand slope and the large Petrie dish cultures proved most efficient in securing the maximum development of azotobacter in pure culture.

Persistence of Anthrax Spores in Raw Water:

E. G. HASTINGS, University of Wisconsin, Madison, Wis.

Anthrax spores have been found to persist for eight years in raw pond water. The longest period of persistence in raw water noted previously was five months; in sterile distilled water thirty months. The water was infected by tannery refuse and growth of the anthrax bacillus had taken place before or after the sample was taken from a stagnant pond. It would seem that the supposition expressed by many that the anthrax organism can grow in nature is true.

Synthetic Media for the Isolation of B. coli from

Water: MAURICE L. DOLT, Brown University, Providence, R. I.

It was found possible to grow *B. coli* on one per cent. solutions of asparagin if 0.2 per cent. of sodium or ammonium phosphate is added. No other of the soluble inorganic salts seemed to serve.

Substances having an asymmetric carbon atom in their molecule and a CHOH group, such as glycerin, ammonium lactate, malic acid, can be substituted for the asparagin. These substances seem to favor the growth of the *B. coli* and to inhibit the growth of other water organisms. It is very likely the presence of this asymmetric carbon atom and the CHOH group in the cholic acid of bile which gives it these same properties.

Every red colony developing on litmus-lactose-agar made up with glycerin, ammonium lactate, or malic acid in addition to ammonium or sodium phosphate was a colony of *B. coli*. On the malic

acid plates only red colonies developed and they were all *B. coli*.

The use of these media in water analysis seems most promising. The presence of *B. coli* even in small numbers can be detected by plating large amounts of the water without preliminary enrichment.

The work is at present being extended to the detection and differentiation of *B. typhosus*.

The complete paper is in the *Journal of Infectious Diseases*, 5, 1908, p. 616.

A Synthetic Medium as a Substitute for Loeffler's Blood Serum in the Diagnosis of Diphtheria: F. P. GORHAM, Brown University, Providence, R. I.

The proteid-free medium which in the liquid form had been found by Hadley to be favorable for the growth and toxin production of *B. diphtheria* was used in combination with agar as a substitute for Loeffler's blood serum. It was as follows:

Glycerin	3.40 parts.
Sodium chloride	0.60 "
Calcium chloride	0.08 "
Magnesium sulphate	0.32 "
Dipotassium phosphate	0.23 "
Ammonium lactate	0.75 "
Ferric phosphate	0.08 "
Glycocoll	0.10 "

Distilled water to make 100 parts, 1.5 per cent. agar, reaction made + 1 with sodium hydrate.

It was found possible to make a diagnosis from swabbings on this medium in less than fifteen hours.

The organisms were of about the same types as on the Loeffler's blood serum, though there was some indication that the granular types were more common on the synthetic medium than on the blood serum.

Note on Roup in Fowls: PHILIP B. HADLEY, Division of Biology, Rhode Island Agricultural Experiment Station.

The present report is based upon the examination of five fowls which died with the characteristic symptoms of "roup." The symptoms and macroscopical pathological appearances were as follows: Onset of disease like simple catarrh; watery exudate from nose and eyes; accumulation of thick mucus or soft, cheesy exudate in orbital sinus, naso-lachrymal canals and palatine space. Walls of mouth cavity and anterior esophagus whitened and necrotic, sometimes punctated with firm, yellowish-white nodules from 1 to 12 mm.

in diameter, and rising from 0.5 to 3 mm. from the surrounding surface; nodules also present in dorsal wall of crop. Esophagus inflamed from crop to proventriculus. Small intestines inflamed and walls thickened, containing mucus mixed with blood. Large intestines usually normal. Ceca inflamed once at necks and once at tips. Liver in two cases contained small white necrotic areas; bile-ducts inflamed and thickened. Kidneys enlarged in one case. Ureters invariably packed with urates, which also fill cloaca. Spleen enlarged in one instance.

The microscopical pathological conditions were studied in fresh preparations, smears and sections. The hard exudate from the orbital sinus was shown to be made up of mucus, coagulated serum and disintegrated cell substance. The soft cheesy matter and the mucus contained numerous epithelial cells, many of which contained coccidia in the schizont or macrogamete stage; these were also found in the free state. Similar bodies were also found in great numbers in the mucus from the naso-lachrymal canals, palatine space, walls of mouth cavity; also from walls of pharynx, anterior and posterior esophagus, dorsal wall of crop, proventriculus, duodenum, bile-ducts, liver, small intestine, large intestine, ceca, contents of cloaca and in the excrement of diseased birds. The encysted stage of the coccidium, which is identical with the organism of "blackhead," was found in the intestines and ceca, but not in the head region.

No bacteriological examinations were made, but it was apparent that the factor, coccidiosis, was sufficient alone to produce nearly all the pathological conditions observed. As "blackhead" is a coccidiosis of the ceca and liver of turkeys, and as "white diarrhea" is a coccidiosis of the ceca, intestines, duodenum and sometimes of the lungs, spleen and liver, of young chicks, so the writer believes that many, and perhaps all, cases of genuine "roup" are instances of coccidiosis of the head region, with or without intestinal complications.

White Diarrhea of Chicks: A Study in Avian Coccidiosis: PHILIP B. HADLEY, Division of Biology, Rhode Island Agricultural Experiment Station.

"White diarrhea" of chicks is a disease affecting the duodenum, small intestines, large intestines, ceca, liver, pancreas, kidneys, spleen and lungs, manifesting itself by inflammation and eventual necrosis of the epithelial, mucosal and submucosal tissues, and terminating fatally in

the majority of cases, primarily as the result of damage to the linings of the alimentary tract, and secondarily as the result of bacterial invasion of the tissues together with suspended constructive metabolism. The aim of the present paper is to show the relation of *Coccidium cuniculi* to this disease.

The macroscopical pathological appearances included the following: (1) occasional inflammation of esophagus and proventriculus; (2) inflammation and thickening of walls of duodenum and small intestines; (3) distention and thickening of walls of the cloaca and large intestine; (4) ceca usually inflamed, walls thickened, and containing a hard or soft yellow exudate or "core"; (5) liver usually contained necrotic areas after the thirteenth day of the epidemic; (6) pancreas occasionally greatly enlarged, and having hard cheesy texture; affection of pancreas, liver and duodenum often coincident; (7) lungs frequently congested, containing grayish nodules; (8) heart frequently contained lobular enlargements; (9) kidneys and ovaries enlarged in a few cases; (10) ureters invariably packed with urates (hence the white diarrhea); (11) yolk sac frequently not properly absorbed, yolk stock occasionally inflamed, walls thickened, containing hardened exudate.

These tissues were examined in fresh preparations, smears and sections, and the microscopical pathological appearances were as follows: (1) epithelial cells of the duodenum, intestines and ceca denuded; (2) in these cells, in the mucous cells and also free were many coccidia; (3) coccidia were also found in the large liver cells from necrotic areas, and free in the connective tissue matrix; (4) nodules from lungs revealed marked inflammation and necrosis; epithelium of bronchi and infundibula broken down, and in the cubical and ciliated cells were inclusions which resemble coccidia.

The bodies described above were the schizont or macrogamete stage of *Coccidium cuniculi*, which is also the cause of "blackhead" in turkeys and of some cases of so-called "roup." This stage of the *Coccidium* is probably identical with the *Amoeba meleagridis* described by Theobald Smith in 1896. In the present epidemic no permanent cysts were found in birds under one month old. It is thus indicated that the original infection passes at once into the endogenous cycle of development which is maintained for some time before the exogenous cycle appears. The crisis of the

disease is coincident with the formation of the sexual products. The highest daily mortality was reached when the chicks were eleven days old. One month after the beginning of the epidemic 304 chicks had died out of 510. The *Bacterium septicemicæ gallinarum* of Rettger was not found in connection with the present epidemic.

Some Experiences Relevant to the Determination of the Bacterial Content of Milk: CHARLES E. MARSHALL, Director, Michigan Agricultural College, East Lansing, Mich.

It is assumed from the observations in the (a) Association Studies conducted by the author and Miss Farrand, in the (b) Butter Studies conducted by W. S. Sayer, Otto Rahn and Miss Bell Farrand and in the (c) systematic work performed by Miss Zac Northrup, all in the bacteriological laboratory of the Michigan Agricultural College, that:

1. Milks vary in their bacterial content as to both (a) numbers and (b) species.

2. This variation is dependent upon the (a) source of the milk, (b) method of milking, (c) cleanliness in handling, (d) temperature maintained, (e) etc.

3. Milks in the light of the above can not develop their germ content (a) with the same rapidity or (b) in the same relative manner, and therefore can not respond *alike* to even ideal or perfect methods of testing.

4. Methods of testing are only incidental to the real problem; they should be employed to indicate and assist in control.

5. While composition of media, means of dilution, time of plating, temperature for plate development and other factors are highly important in the execution of these tests, the most essential factor at this time is uniformity of methods that the variable minor discordant elements may to a large extent counteract each other through the accumulation of evidence.

6. It follows that the purpose of the Committee on Standard Methods of Bacterial Milk Analysis is justified, even though many of its detailed decisions are arbitrary and perhaps unwarranted should uniformity of methods be established.

7. However, much would be sacrificed if laboratory men forgot the real purport of such analyses and used them simply to estimate the milk per se instead of the conditions which are indicated by such analyses.

It is suggested that perhaps more rapid progress would be made and more enduring results secured were the energies of workers devoted to more

exhaustive elemental studies which will assist in the solution of some of these problems.

Cremating Furnace for Laboratories: CHARLES E. MARSHALL.

It consists of an open brick chimney, lined with fire brick on the inner wall, and with an air space between the inner and outer walls. At the bottom of the chimney are the cremating apartment, the fire box and the ash pit. The essential and valuable feature of the cremating chimney is the using of gas pipes for grates to support the material, thus enabling the placing of a fire below. These pipes are so inserted in collars communicating with the air outside that a cold current of air passes through when heated and passes into the chimney at the inner end of the pipes which rest on a ledge on the inner wall of the chimney.

Published by the Experiment Station Report of the Michigan Agricultural College for 1908.

Preparation of a Standard Solution of Litmus: CHAS. W. BROWN, Michigan Agricultural College, East Lansing, Mich.

It was found that 2.5 grams of azolitmin dissolved in one hundred cubic centimeters of distilled water would give a solution of such strength that one cubic centimeter when added to one hundred cubic centimeters of milk would give a blue color of the intensity desired for litmus media. With this as a measure, thirteen samples of litmus were standardized, giving the numbers recorded in the table.

Sample	Grams Required to make 100 c.c. of Standard Solution	Per Cent. Insoluble
Azolitmin	2.5	0
Merck's purified	7	2.3
Soluble litmus	8	14.5
Litmus cubes	140	87.1
No. 1	15	44.3
No. 2	32	68.7
No. 3	68	81.4
No. 4	98	89.4
No. 5	128	92.8
No. 6	164	92.8
No. 7	110	91.5
No. 8	154	94.3
No. 9	146	91.7
No. 10	122	91.8

A definite amount of the sample was weighed out and dissolved in a definite volume of distilled water, either by placing in an incubator at 37.5° C. over night or by heating in flowing steam for thirty minutes. The filtrate was compared in Nessler's tubes with the standard solution

(2.5 gra. of azolitmin in 100 c.c. water) diluted one to five thousand—one or two drops of decinormal potassium hydrate was added to each Newaler's tube to bring out the color. From this comparison the number of grams required to make one thousand cubic centimeters of a standard was interpreted.

Variation in the Acidity of Fresh Milk: W. M. ESTEN, Storrs Agricultural Experiment Station, Storrs, Conn.

The extreme variation, of a herd of 26 cows, covering a period of seven months, was from .075 to .23 per cent. The samples of milk were taken about every fortnight. The method of testing the acidity was by titration with $\frac{1}{10}$ normal NaOH, using 17.6 c.c. of milk and dividing the amount of tenth normal by 20. This result gives the per cent. of acidity in terms of the lactic acid molecule. The samples of milk were collected from each cow in the morning from 5 to 6 and were titrated about 10 A.M. In the interval, after a vigorous shaking, 2 c.c. of milk were taken from each sample for the bacteriological test. The experiments commenced on May 16 and extended to December 16. When curves were plotted and drawn for each cow, for different breeds of cows, for averages of breeds and for all the cows collectively, it was discovered that individual cows varied in their own curve and from the curves of the other cows, and that the breeds markedly varied from one another. There was also indicated for every cow a marked decrease in acidity during the summer, and a marked increase during the winter months. The food and seasonal period seemed to be controlling factors in the variation. The eleven Jerseys had an average acidity of .18 per cent., while the Holsteins had an average acidity of .16 per cent. The individual Jerseys showed a larger variation than the individual Holsteins, indicating that the Jerseys are more susceptible to changes and have a more sensitive nervous temperament. The total average of 378 tests on 25 cows was precisely .17 per cent., a value which gives a fairly correct idea of the normal acidity of milk.

Some of the most marked variations in acidity were found among the Jerseys and one Guernsey. One Jersey had an acidity of .13 per cent. at the close of her lactation period and commenced the next with an acidity of .2275 per cent. Three other Jersey cows had acidities of .22, .225 and .23, respectively, as their highest extremes. These cows were apparently in perfect health. It was found that pathological conditions had an effect

on the variation of acidity instanced during the summer by a cow with a sore foot. This cow's milk showed a drop to .125 on July 8, a rise to .18 on July 27 and a drop to .135 on August 7. After her recovery her milk acidity rose to .19 and varied afterwards but little. All these results lead to the conclusion that certain factors of food, conditions of health and the change of seasons have their effects, which are shown in the changes of acidity in the milk. A Guernsey had the most remarkable variation of all. Her average was only .108 with variations from .075 to .13. This is the lowest extreme in acidity that has, to the writer's knowledge, been recorded.

The question arises, What are the neutralization elements which we call acidity of milk? Is it the caseinogen alone, or caseinogen combined with other compounds, that causes the reactions? It has been suggested that the amount of acidity is an indirect indicator of the amount of caseinogen present. If this be true the acidity test would be a simple and rapid determination for the approximate amount of caseinogen present. It is to the chemist that we must submit the problem for solution.

Cost of Heating an Incubator with Electricity: W. M. ESTEN, Storrs Agricultural Experiment Station, Storrs, Conn.

There are two important factors which determine the economic application of electricity in the heating of incubators for constant temperatures, namely, the insulation and the heating and regulation devices.

Copper is universally used in constructing incubators for laboratory use. With the exception of silver, copper is the best conductor of heat known. The insulating material used with copper is imperfect and not properly applied for preventing loss of heat. Copper incubators are generally water-jacketed and leaks often arise, causing disagreeable annoyances. The duration of the copper is somewhat limited. If such materials as asbestos, hair felt, wood and cork board are selected and used in combination there can be constructed an incubator, fire proof, with almost perfect insulation, and practically indestructible, at about one quarter the cost of a copper incubator. Moreover, the diminished cost of operation will pay for its construction cost in a few years. The writer has constructed one of these incubators out of asbestos, wood, hair felt and building paper with an inside capacity of three and a half cubic feet, which costs less than one dollar a year to heat to a constant temperature of 37° C.

The thermostat is constructed in the form of a V out of strips of brass and hard rubber firmly fastened together. The coefficients of expansion and contraction of brass and hard rubber are very different. Any change of temperature either opens or closes the electrical contact on the right-hand side of the V. The most important item in the economy of this new style of incubator is that the heat is applied to the interior, where it is used and needed. Incubators heated by gas utilize only about half the heat applied, and there is, besides, the danger of fire in operation.

The most satisfactory heater is made of No. 29 30 per cent. alloy german-silver resistance wire wound on a frame which fits into one end of the incubator. Two frames, one in each end, with 58 feet of wire on each frame and connected as one coil, afford the most uniform method of heating. The wire can be obtained from the American Electrical Works, Providence, R. I. The cotton-wound wire is preferable, for it affords considerable insulation. When the heating coils are completed a coat of shellac on the wire and frames serves as an added insulation. The resistance of the wire is 229.9 ohms per 100 feet. The only current that can be used with satisfaction is the alternating or incandescent type with large volume and low intensity. The voltage should be 110 for the length of wire indicated, which will produce about .4 ampere of current.

Keeping Qualities of Butter—Additional Data:
OTTO RAHN, Michigan Agricultural College,
East Lansing, Mich.

Former experiments have proved that rancid cold-storage butter does not necessarily have free acids—indeed the majority of samples had no increased acidity. It seemed probable that the substances causing the taste and odor of rancid butter come from a decomposition of protein. The organisms which in pure culture are able to make butter rancid, such as *Bacillus fluorescens liquefaciens*, *Bacillus prodigiosus*, *Oidium lactis*, etc., break down proteids easily. The analytical determination of soluble nitrogenous substances, not precipitated by tannin, copper sulphate nor phosphotungstic acid, gave the highest increase in the butter sample which scored lowest.

Experiments have been carried on to ascertain if unsalted butter did not keep better in cold storage than salted butter. The supposition was that the water and buttermilk of the unsalted samples would freeze, thus preventing any action of microorganisms, while the concentrated brine

of salted butter has a very low freezing point. The result was that the unsalted samples did not keep, probably because not all the water was frozen. The unsalted samples scored lower and showed a greater increase of soluble nitrogen.

The only microorganism which multiplied without doubt in cold-storage butter and which occurs in almost every butter sample, is a small *Torula*. This *Torula* is the only microorganism of our butter samples which can develop on agar with 15-30 per cent. salt. A small *Torula* has been found by Rogers in fishy butter. A *Torula* is present almost in pure culture in salted herring and may be the cause of its characteristic taste and odor. The description of the *Torula* is incomplete, however, they do not disagree.

Bacillus lactimorbi, Jordan and Harris (nova species)—*Its Relation to Milk-sickness and Trembles*: E. O. JORDAN and N. MACLE HARRIS, University of Chicago, Chicago Ill.

This organism appears to be a hitherto undescribed bacterium and was isolated by the writers from several cases of trembles in cattle, from one case of the disease in a horse, from two lambs and from four cases of milk-sickness in the human subject. It would seem that the disease in man is incurred through the ingestion of infected milk, milk-products or of meat; in animals by the eating of infected pasturage or by drinking infected water, the contamination of these being from the soil in which the bacterium has its abode.

By means of pure cultures the writers have succeeded in reproducing the essential features of the naturally acquired disease in young rabbits, dogs, calves and one horse; cats and lambs have been infected with the production of pathological lesions, but without any well-defined clinical symptoms.

The organism causing the disease is a strict aerobic, flagellated, sporing, liquefying bacillus about the size of the anthrax bacillus, and very strongly resembling the tetanus bacillus in its most characteristic form. It is, however, very prone to undergo considerable variation in morphology due to methods of cultivation, temperature and fluctuations in reaction of the media being chiefly responsible. Stained with methylene blue the typical tetanus-like bacillus shows well-marked polar metachromatic granules, with at times a central one. It grows either very vigorously or delicately on agar, depending upon whether it is incubated at 25°, 30° or 37° C. Colonies on agar are of a streptococcus type accompanied by a film growth of a delicate nature,

either on the top or on the bottom of the agar surfaces. In glucose agar stab tube no gas is formed and the stab growth is smooth, delicate and whitish. On potato no growth has been obtained, but on Heinemann's synthetic potato medium a so-called "invisible" growth occurs. Broth is moderately clouded and occasionally a delicate surface film is formed. In gelatin the stab extends nearly all the way down the needle-track in a smooth, even manner and of a grayish color; the surface growth is scant, delicate and pearly gray; a saucer-shaped zone of liquefaction makes its appearance upon the surface about the third to the tenth day, and progressively extends outwards and downwards until the whole of the gelatin is liquefied. Occasionally where liquefaction has been delayed feathery outgrowths from the stab have been observed. In litmus milk growth does not readily occur unless the medium has been heavily seeded, then a slow-appearing alkaline reaction makes itself noticeable about the third day at the surface of the medium, which later on extends throughout the tube, eventually rendering the milk semi-translucent; no clotting or proteolytic changes have ever been seen. On Jordan's asparagin medium a well-marked surface film growth takes place with an ultimate slight clouding of the whole medium.

Note on a Lactic Acid Forming Bacillus Closely Resembling B. bulgaricus Isolated from Cornmeal. P. G. HEINEMANN and MARY HEFFERN, University of Chicago, Chicago, Ill.

During an investigation of yeasts for the preparation of so-called salt-rising bread a bacillus was isolated which, as far as the examination has proceeded, agrees in morphology, staining properties, cultural characteristics and the ability to produce large amounts of lactic acid from milk with the characteristics of *B. bulgaricus*, the organism which has recently received considerable attention and has been recommended by Metchnikoff for the preparation of sour milk. A stain from the mixture of cornmeal, milk, sodium bicarbonate and salt showed a large number of bacilli with the characteristic granular staining of Metchnikoff's bacillus. After cultivation in milk the bacilli stained uniformly. When granules appear the picture recalls somewhat the appearance of small spores and seems to agree with Kuntze's description of his "Körnchen" bacillus. Attempts to obtain these bacilli in pure culture by plating on the ordinary laboratory media failed utterly, but they were readily isolated if cultivated in milk at 37° C. or if plated on milk-agar. The colonies

after a few days have peculiar root-like ramifications on milk-agar and may be mistaken for small colonies of *B. subtilis*. In pure culture the milk is coagulated slowly, rarely in less than two or three days. The coagulum is soft and creamy, without the separation of whey, and unlike the more solid coagulum formed by *Streptococcus lacticus*. The amount of lactic acid produced in milk is much higher than the amount produced by *S. lacticus*. After fourteen days 1.65 per cent. acid was determined. By addition of glucose or lactose to ordinary agar a moderate growth appeared after two or three days. If this bacillus is sowed into sterile milk with a culture of *S. lacticus*, acid is formed more rapidly than by either of the two organisms alone and the coagulation of the casein is also more rapid.

Salt-rising bread is started by mixing cornmeal, milk, sodium bicarbonate and salt. It seems that milk is a necessary part, without which probably the bacillus is unable to grow and form the necessary lactic acid for liberating carbon dioxide from sodium bicarbonate. By inoculation of sterilized milk with cornmeal it was ascertained that the bacillus originated from the cornmeal and not from the milk. It is, therefore, quite possible that this bacillus is widely distributed and an investigation is now under way to determine the distribution. We are attempting to isolate this bacillus from a large variety of sources, principally flours, dry fodder, silage, feces of man and domestic animals, sourkrout and other similar substances. The study has extended over a period of a few weeks and we hope to be able to make a more complete report in the near future.

The Gas Production of B. coli: FREDERICK G. KEYES, Brown University, Providence, R. I.

All previous work on gas production has been of little value because of imperfect methods of collecting and analyzing the gases produced.

The ordinary fermentation tube does not give the exact amounts of gas produced because of the solution of the gases in the medium and its diffusion therefrom.

The methods ordinarily used by the bacteriologist for analyzing the gases produced are imperfect because they give merely the CO₂ content and tell little about the other gases which may be present. Also, standard media, even at best, are sufficiently variable to influence materially the amount and composition of the gases produced.

Therefore the writer set about to devise an apparatus which would enable him to collect and

analyze all the gases produced by an organism on a synthetic medium containing substance of known chemical constitution. The results of the use of this apparatus for studying the gas production of *B. coli* are as follows:

	Time in Hours at 37° C.	Total Gas in Per Cent.	CO ₂ Per Cent.	H Per Cent.	N Per Cent.
On a synthetic medium in vacuum.	24	28.6	63.36	36.6	0.05
	72	45.7	63.40	36.15	0.45
	116	96.3	63.56	35.94	0.50
On standard medium in vacuum.	48	197.1	55.87	43.50	0.65

The Utility of the Society's Card in Classifying the Cheese Flora: H. A. HARDING and M. J. PRUCHA, New York Agricultural Experiment Station, Geneva, N. Y.

During the past four years the flora of American cheddar cheese has been intensively studied at the New York Agricultural Experiment Station. In connection with this study an attempt has been made to classify the organisms which were found in nine normal cheeses and so characterize them that they may be recognized by succeeding students.

During the progress of this study there appeared a classification of the bacteria of milk by Conn, Esten and Stocking. This work was of material assistance to us and covered the milk flora so completely that all but one of the organisms found by us in cheese is evidently included under the types described by them. This classification as arranged by Conn is an adaptation to bacteria of the conventional botanical system of classification.

The society's card has also appeared during this interval and the cheese flora has also been arranged in accordance with its system of group numbers.

As the result of this double classification the germs found represent 22 types according to Conn or 33 groups according to the society's card. The classification of the germs found in nine normal cheddar cheeses according to each of these systems is given in the accompanying table. This table is taken from Technical Bulletin No. 8, New York Agricultural Experiment Station, in which are given the details of this study.

The amount of data required to determine the group number and the type name is practically the same, but a careful comparison of the utility of these two systems in connection with this study is strongly in favor of the society's card.

This advantage lies in the increased accuracy with which different workers assign germs to like groups, in the quickness with which such assignment can be made and in the ease with which duplicates can be detected or the accumulated stock of records be consulted.

By the use of the card the results of one worker are made immediately available to succeeding workers and each can recognize the forms which have been already described and build upon the foundation already laid. By accumulating results in this way, it will soon be possible to have as exact a knowledge of the bacterial flora of any given class of objects as we now have of the higher flora of a region.

It is believed that the introduction of the society's card will prove the most important addition to laboratory and classification technique since Robert Koch brought out the gelatin plate.

Autolysis of the Gonococcus: C. T. MCCLINTOCK, M.D., Ph.D., and L. T. CLARK, B.S., from the Research Laboratories of Parke, Davis & Co., Detroit, Mich.

Autolysis of gonococcus cultures has been observed and reported by numerous workers.

The purpose of the present study is: (1) to confirm the results obtained by others; (2) to determine the amount of ferment present, the method by which it breaks up the cells and the extent to which the action can be carried; (3) to determine the effect of the resulting autolysate on the growth of the gonococcus, and other organisms in vitro, and (4) to study the effect of the autolysate on the organisms in vivo and its possible therapeutic application.

The results obtained so far are shown in the following conclusions:

Disintegration or autolysis occurs in gonococcus cultures to a marked degree.

This autolysis can be completely prevented by heat alone at 70° C. for one hour, by heat in the presence of trikrisol at 60° C. for one hour, by 50 per cent. and 95 per cent. alcohol in salt solution and partially by 4 per cent. trikrisol alone.

Specimens stained at certain stages of disintegration show numerous fragmentary cell walls still capable of taking the stain, indicating that the cell wall is not completely disintegrated.

The presence of shadow forms in which the cell wall only is stained indicates that the cell contents are either so changed as to be incapable of taking the stain or have escaped from within the wall.

The presence of soluble proteid substances (as shown by their precipitation with acetic acid) in the surrounding liquid indicates that the contents have escaped from within the cell.

Hence it would seem that autolysis of the gonococcus is affected by rupture of the cell wall and escape of the contents.

The products of this autolytic process markedly inhibit the growth of the gonococcus on artificial culture media. Their use in combating the disease in man will form the subject of a future communication.

A Case of Non-inheritance of Fluctuating Variations among the Bacteria: C.-E. A. WINSLOW and L. T. WALKER, Massachusetts Institute of Technology, Boston, Mass.

Aside from its practical importance, the study of variation among the bacteria promises to throw important light upon some of the fundamental biological problems of heredity and evolution. It is important to distinguish two types of possible variations, those which arise entirely from causes operating within the bacterial cell (either mutations or fluctuating variations), and those which are apparently due to the direct or selective effect of the environment. Goodman¹ has recently demonstrated that by selection of variations of the latter sort the acid production of certain members of the diphtheria group of bacilli may be profoundly modified. In the present investigation the authors have attempted to study the inheritance of fluctuating variations in the paratyphoid group, without special selective action. Cultures of Schottsmüller's types A and B were plated out and one hundred subcultures of each were inoculated on agar from separate colonies. A dextrose broth was inoculated from each streak. The reduced were determined by titrating ults, when plotted, showed two distinct frequency curves of frequency with means 1.1 for type A and 1.6 for type B. The agar the four extreme cultures (1.1 and 1.6 for type A and 1.4 and 1.8 for type B), were then a series of one hundred streaks made. The new curves of frequency for these revert completely to the original

of Infectious Diseases, V., 421.

means of types A and B, showing no inherited effect of the variations exhibited by their more immediate ancestors.

Bacteriology as an Important Non-technical Study: H. W. HILL, M.D., University of Minnesota, Minneapolis, Minn.

Bacteriology is now chiefly taught as an art, of use in some branch of science or industry, and almost wholly for its applications in these. Bacteriology is seldom studied for itself alone. But it presents many most important biological lessons, as suitable for the illustration of biological truths as any other biological study now taught; and from the control of conditions possible, some phases of biology can be illustrated best by bacteriology. For sociology, bacteriology permits, as no other biological study does, the appreciation not only of the unit, but of the interrelations of units—and hence furnishes a biological study closely paralleling sociology itself. (As a weapon in the hands of a sociologist dealing with hygienic problems it is of course practically a necessity.) Apart from its academic values its chief practical significance to the non-technical citizen consists in the training it gives concerning the nature, distribution and life history of bacteria and in its technique, which teaches the fundamentals of personal and family defense against disease, as distinguished from the measures of public health or state medicine. For these reasons bacteriology should be taught in the public schools, since diffusion of its teachings through the citizens in general can not be obtained in any other way.

NORMAN MACL. HARRIS,
Secretary

UNIVERSITY OF CHICAGO

SOCIETIES AND ACADEMIES

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE

The thirty-third meeting of the society was held at Cornell University Medical College, April 21, 1909, with President Lee in the chair.

Members present: Atkinson, Auer, Burton-Opitz, Elser, Ewing, Flexner, Famulener, Gies, Janeway, Joseph, Kast, Lee, Lamar, Lewis, Lusk, Mandel (J. A.), Meltzer, Meyer, Morse, Noguchi, Norris, Oertel, Park, Pearce, Shaffer, Storey, Terry, Wallace, Wolf.

Members elected: John L. Todd, Peyton Rous, H. S. Jennings, Andrew Hunter, Charles R. Stockard, E. E. Southard, William W. Hale.

Scientific Program

R. Burton-Opitz: The vascularity of the spleen as influenced by single nerves of the plexus lienalis.

Richard M. Pearce: An experimental study of the influence of kidney extracts and of the serum of animals with renal lesions upon the blood pressure.

J. J. R. Macleod: Further observations on the effect of asphyxia and curare on the reducing power of the blood after section of the hepatic nerves in dogs.

William H. Park and Eugene Famulener: Toxin-antitoxin mixtures as immunizing agents.

Alfred F. Hens: Antiperistalsis in its relation to tubercle bacilli and other bacteria in the alimentary tract.

Simon Flexner and Richard V. Lamar: The action of soaps on the pneumococcus.

A. O. Shaklee and S. J. Meltzer: The influence of shaking upon trypsin and rennin and a comparison of this influence with that upon pepsin.

Don R. Joseph and S. J. Meltzer: The influence of sodium and calcium upon direct and indirect muscle irritability and their mutual antagonistic actions.

J. Auer and S. J. Meltzer: The effects of local application of chloride and sulphate of magnesium upon the centers in the medulla compared with those of sodium chloride.

J. Auer and S. J. Meltzer: Respiration by continuous intrapulmonary pressure without the aid of muscular action.

Alexis Carrel: Note on the production of kidney insufficiency by reduction of the arterial circulation of the kidney.

Theodore C. Janeway: A modification of the Riva-Rocci method of determining blood-pressure for use on the dog.

Theodore C. Janeway: Note on the blood-pressure changes following reduction of the renal arterial circulation.

H. C. Thacher: The effect of experimental acute insufficiency of the right heart upon the volume of the organs.

The thirty-fourth meeting of the society was held at the Rockefeller Institute for Medical Research, May 26, 1909, with President Lee in the chair.

Members present: Auer, Beebe, Ewing, Famulener, Flexner, Gies, Hatcher, Joseph, Lee, Lewis, Loeb (Leo), Morse, Meyer (Gustave), Pearce,

Shaffer, Sherman, Terry, Van Slyke, Wallace, Well, Wolf.

Members elected: C. W. Edmunds, J. W. Draper, Maury, Adolph Meyer.

By-law Adopted: One of the regular meetings may be held annually outside of Greater New York.

Scientific Program

H. Gideon Wells and Harry J. Corper: Observations on uriccolysis, with particular reference to the "uric acid infarcts" in the kidneys of the new born.

L. L. Woodruff: Further studies on the life cycle of paramoecium.

W. O. Emery and William Salant: On the decomposition of caffeine in the liver.

William Salant: The comparative toxicity of ethyl and amyl alcohol and their effect on blood pressure.

L. B. Stookey: Pentosuria.

Elizabeth Cooke and Leo Loeb: The comparative toxicity of sodium chloride and of fluorescent staining solutions upon the embryos of *Fundulus*.

M. S. Fleisher and Leo Loeb: The influence of calcium chloride and of adrenalin upon the secretion of urine and upon resorption from the peritoneal cavity.

Benjamin T. Terry: Immunity to various species of trypanosomes induced in mice by the cure of experimental infections.

D. D. Van Slyke and P. A. Levene: On the leucin fraction in casein and edestin.

D. D. Van Slyke: On "Clarin," Vahlen's active principle of ergot.

Daniel R. Lucas (by invitation): Some effects of sodium benzoate.

Matthew Steel (by invitation): An improvement of the Folin method for the determination of urinary nitrogen.

P. A. Levene and W. A. Jacobs: On uric acids.

Gustave M. Meyer and P. A. Levene: On the behavior of amino acids and glyoxylic anhydride in the organism of the dog.

I. Levin, D. Manson and P. A. Levene: Nitrogenous metabolism in dogs with terectomy.

R. M. Pearce: The depression of uric acid in urine; its disappearance in experimental nephritis.

Philip A. Shaffer: Observations on osmotic pressure in a subject of diabetes.
